Abstract:

The combination of rituximab, bendamustine, and low dose cytarabine (R-BAC) has been studied in a phase 2 prospective multicenter study from the Fondazione Italiana Linfomi (FIL RBAC500). In 57 previously untreated elderly patients with mantle cell lymphoma (MCL), R-BAC was associated with complete remission rate of 91%, and 2-years progression free survival (PFS) of 81% (95%CI 68-89). Here, we report the long-term survival outcome, late toxicities, and results of minimal residual disease (MRD) evaluation. After a median follow-up of 86 months (57-107), the median overall survival (OS) and progression-free survival (PFS) were not reached. The 7-years PFS and OS rates were 55% (95%CI 41-67), and 63% (95%CI 49-74), respectively. Responding patients (n=53) had a 7-years PFS of 59% (95%CI 44-71), with no relapse or progression registered after the 6th year. At multivariate analysis blastoid/pleomorphic morphology was the strongest adverse predictive factor for PFS (p=0.04). Patients with an end of treatment negative minimal residual disease (MRD) had better, but not significant, outcomes for both PFS and OS than MRD positive patients (p=0,148 and p=0,162, respectively). There was no signal of late toxicity or increase of secondary malignancies during the prolonged follow-up. In conclusion, R-BAC, which was not followed by maintenance therapy, showed sustained efficacy over time in elderly patients with MCL. Survival outcomes compare favorably with other immuno-chemotherapy regimens (with or without maintenance), including combinations of BTK-inhibitors upfront.

Key Points:

1. R-BAC was associated with high rate of sustained remissions in elderly patients with MCL
2. After 7-years of follow-up, median overall survival and progression-free survival were not reached, with no signal of late toxicity

Abstract

The combination of rituximab, bendamustine, and low dose cytarabine (R-BAC) has been studied in a phase 2 prospective multicenter study from the Fondazione Italiana Linfomi (FIL RBAC500). In 57 previously untreated elderly patients with mantle cell lymphoma (MCL), R-BAC was associated with complete remission rate of 91%, and 2-years progression free survival (PFS) of 81% (95%CI 68-89). Here, we report the long-term survival outcome, late toxicities, and results of minimal residual disease (MRD) evaluation.

After a median follow-up of 86 months (57-107), the median overall survival (OS) and progression-free survival (PFS) were not reached. The 7-years PFS and OS rates were 55% (95%CI 41-67), and 63% (95%CI 49-74), respectively. Responding patients (n=53) had a 7-years PFS of 59% (95%CI 44-71), with no relapse or progression registered after the 6th year. At multivariate analysis blastoid/pleomorphic morphology was the strongest adverse predictive factor for PFS (p=0.04).

Patients with an end of treatment negative minimal residual disease (MRD) had better, but not significant, outcomes for both PFS and OS than MRD positive patients (p=0,148 and p=0,162, respectively). There was no signal of late toxicity or increase of secondary malignancies during the prolonged follow-up.

In conclusion, R-BAC, which was not followed by maintenance therapy, showed sustained efficacy over time in elderly patients with MCL. Survival outcomes compare favorably with other immuno-chemotherapy regimens (with or without maintenance), including combinations of BTK-inhibitors upfront. This study is registered with EudraCT 2011-005739-23, and ClinicalTrials.gov NCT01662050.

INTRODUCTION

Mantle cell lymphoma (MCL) is an aggressive histotype of non-Hodgkin lymphoma (NHL), characterized by continuous relapses over time, and no standard front-line therapy. Therapeutic choices for transplant ineligible patients are represented by R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisolone), or bendamustine and rituximab (BR)¹⁻³, both followed by rituximab maintenance^{4,5}.

As compared to R-CHOP, BR has currently been recommended as the preferred first-line regimen in contemporary clinical practice guidelines⁶. The R-BAC regimen, which is based on the addition of intermediate dose cytarabine to BR⁷, has also been included in clinical guidelines^{6,8}. This combination **has been supported by** preclinical studies showing that bendamustine and cytarabine have distinct and synergistic mechanism of action, especially when administered sequentially⁹. Between 2012 and 2014, the Fondazione Italiana Linfomi (FIL) conducted a phase 2 multicentre trial (RBAC500)⁷, analyzing the efficacy and safety of the R-BAC regimen (rituximab, bendamustine and intermediate dose cytarabine) in patients with MCL not eligible to autologous transplant. R-BAC was not followed by rituximab maintenance. The primary analysis of the study, with a median follow-up of 35 months, reported high CR rate (91%) with 2-years overall survival (OS) of 86% (95%CI 74-93), and progression-free survival (PFS) of 81% (68-89). Despite this relevant antitumoral activity, R-BAC was more toxic than BR, particularly in terms of hemato-toxicity between cycles. A recent real-life report confirmed that R-BAC was significantly more effective than BR, but more toxic, with doses that were frequently reduced to spare hemato-toxicity¹⁰. Finally, the phase 3 randomized SHINE study has shown that the addition of

ibrutinib to BR, as compared to placebo, followed by double maintenance, significantly improved PFS of elderly patients with MCL¹¹. With this in mind, we performed a long-term analysis on the efficacy and toxicity end-points of the RBAC500 trial.

METHODS

Study design and participants

RBAC500 was a multicenter, single arm, phase 2 study, recruiting previously untreated patients with confirmed histological diagnosis of MCL. The study involved 29 FIL centers. To be included patients had to be older than 65 years and fit according to the comprehensive geriatric assessment, or aged 60–65 years if they were ineligible for high-dose chemotherapy plus autologous stem-cell transplantation, fit or unfit according to the comprehensive geriatric assessment (for the modified comprehensive geriatric assessment, see appendix p.2 of the original report)⁷. The diagnostic criteria of MCL included positivity for cyclin D1 and SOX11 expression [mandatory in patients who were cyclin D1 expression or t (11;14) negative]. Patients with in-situ MCL or non-nodal leukemic disease were excluded; for the complete list of inclusion and exclusion criteria see the original report⁷.

The study was conducted in accordance with the principles of the Declaration of Helsinki and Good Clinical Practice. Ethics approval was granted by the institutional review board at each participating institution, and all patients provided written informed consent.

This study was registered with EUDRA-CT, number 2011-005739-23, and ClinicalTrials.gov, number NCT01662050.

Procedures

Baseline assessment included bone marrow biopsy, tumor staging with contrast-enhanced CT, and PET. Paraffin blocks of the diagnostic specimen were collected for central pathological review, which were performed by expert hematopathologists (SAP), according to criteria of the WHO Classification¹². All patients received RBAC500 (rituximab 375 mg/m² on day 1; bendamustine 70 mg/m² over 30–60 min on days 2 and 3; cytarabine 500 mg/m² over a 2 h infusion starting 2 h after bendamustine on days 2–4; all administered intravenously) every 4 weeks for up to six cycles. No patient received rituximab maintenance. Prophylaxis and toxicity management were described in the original paper⁷, with granulocyte colony-stimulating factor (G-CSF) that was mandatory following each cycle. Patients who did not respond to the first two cycles were discontinued from the study. Response assessment was according to Lugano criteria¹³. Follow-up including clinical evaluation, laboratory tests, and CT scan was performed every 3 months for the first year after end of treatment, and then every 6 months for 2 more years. After the third year, patients were followed up with visits according to the local hematologists. It was demanded that patients were seen at least 2 times per year for clinical examination and blood tests. CT-scan was mandatory for any clinical suspicion of relapse or appearance of adenopathies or organomegaly or alterations of the blood exams. Queries were sent to the centers twice a year by FIL offices to update the state of disease and inform on late toxicities or secondary malignancies (SM).

Centralized assessment of minimal residual disease (MRD) was performed in the EuroMRD standardized laboratory of the University of Torino (Torino, Italy) at diagnosis, before cycle 3, and at 1 month, 6 months, 12 months, and 24 months after the end of treatment. We used ASO-droplet digital polymerase chain reaction (ddPCR) analysis¹⁴ to assess MRD in bone marrow (BM) and peripheral blood (PB) samples, using patient-specific primers and consensus probes to detect the immunoglobulin heavy-chain (IGH) variable region gene rearrangement or the IGH::BCL1 product of the t (11;14) translocation. The sensitivity of MRD detection by ddPCR was 2E-05, allowing the detection of a single event among 75000 cells analyzed. For survival analysis a positive sample in at least one of the tissues analyzed (either BM or PB) defined MRD positivity.

Primary efficacy and safety outcomes were reported in the original paper. For the purpose of the present paper we estimated long-term OS and PFS as primary efficacy outcomes. Toxicity was analyzed in terms of secondary malignancies, or any other toxicity reported by investigators during the follow-up period.

Statistical analysis

Demographics and clinical patient characteristics were summarized with descriptive statistics. PFS and OS were estimated using the Kaplan–Meier method and the groups were compared using log-rank test. Overall survival from the progression of disease - POD (OS-2), was defined as time from POD until death due to any cause. Multivariable analysis was performed using Cox regression models. Toxicity, completed treatment rates and treatment response rates were compared with the chi-square or Fisher's test. Cumulative incidence of SM was estimated using the method proposed by Gooley et al.¹⁵, considering death from any cause as a competing event.

RESULTS

Demographic features, cycles delivery, dose reductions

Between May 2012 and Feb 2014, 57 patients from 29 centers were consecutively enrolled in the RBAC500 trial. The main characteristics of these patients, whose median age was 71 years (range, 61 to 79), were described in the original report⁷. Briefly, 25 patients (44%) had high risk MIPI, 16 (31%) had $ki67 \geq 30\%$, and 14 (25%) had blastoid/pleomorphic morphology. No patient had non-nodal leukaemic disease, as for inclusion criteria. Overall, 54 (95%) received at least four cycles of RBAC500, and 38 (67%) had six cycles, with a median of 6.0 (range 2–6) cycles per patient (for distribution of patients and treatment see figure 1, "Trial Profile" from the original report⁷). The majority of patients (75%) had dose reductions of the R-BAC regimen as per-protocol, which mostly consisted in avoiding the 3rd day of cytarabine.

Efficacy outcomes

As previously described, all responding patients achieved CR (52, 91%). Two patients (4%) had progressive disease during induction, while 3 patients (5%) were considered not responders because of early treatment interruption due to toxicity.

At the time of the present report, after a median follow-up of 86 months (range 57-107), 35 patients (61%) are still alive, while 22 patients died (39%). The median OS and PFS have not been reached (Figure 1A-1B). The 7-years PFS and OS rates were 55% (95%CI 41-67) and 63% (95%CI 49-74), respectively. The 7-years duration of response (DOR) of the 52 responding patients was 59% (95%CI 44-71, Figure 1C).

At univariate analysis, adverse predictive factors affecting PFS were high risk MIPI ($p=0.04$), Ki67 $\geq 30\%$ ($p<0.001$), blastoid/pleomorphic morphology ($p<0.001$), (Figure 2A, 2B, 2C, respectively), and failure to achieve CR at the end of treatment ($p<0.001$). Patients who had 4 cycles had similar PFS than those completing full treatment (6 cycles), as no difference was observed between patients having dose reductions as per-protocol along cycles ($p=0.2$ for both).

At multivariate analysis, after computing variables that were significant at univariate analysis, morphology (blastoid/pleomorphic variant) resulted the strongest risk factor for PFS (HR 3.12, $p=0.04$, 95%CI 1.05-9.28), Table 1.

Long term side effects, SM and cause of deaths

There were 22 registered deaths during the study period. The majority of them (17, 77%) were due to lymphoma progression, while remaining five (23%) were due to other causes (two to SM, two to sepsis and one to a septic shock in secondary acute myeloid leukemia). No other late toxicity was addressed as possibly related to the induction treatment.

During follow-up, six patients developed SM: 1 prostate cancer, 1 bladder cancer, 2 head and neck cancer (1 larynx, 1 thyroid), 1 lung cancer and 1 secondary acute myeloid leukemia. The cumulative incidence of SM at 7 years was 11.2% (95% CI 4.5-21.3), and the median time to SM was 68 months (range 55-91), Figure S1.

Salvage therapy

Of the 25 patients that were refractory or relapsed, three (12%) did not receive any further treatment due to rapid deterioration of clinical status. Six (24%) had ibrutinib monotherapy as second line, of whom four responded (3 still in CR). The remaining 16 patients received miscellaneous treatment, (7 had R-CHOP or R-CHOP-like, 3 had BR, 1 had high dose-methotrexate for central nervous system relapse, 2 had lenalidomide, and 3 patients received radiation therapy).

Overall, OS from time of first relapse (OS-2) was 8.9 months (range 0-61.9 months) (Figure 3A). The median OS-2 for patients treated with ibrutinib was longer, albeit not significantly, than for patients treated with other approaches [2y OS-2 63% (95%CI 14-89) vs 36% (95% CI 11-63), $p=0.16$; Figure 3B].

Furthermore, patients that were refractory to induction therapy or who experienced progression of disease (POD) within 24 months (POD-24, $n=10$), had significantly inferior OS-2 than patients with late-POD [22% (95% CI 3-51) vs 53% (95% CI 21-78), $p=0.02$, figure 3C].

Minimal residual disease

Of 57 patients, 45 (79%) had a molecular marker (29 IGH rearrangement, eight IGH::BCL1 target and eight had both). Follow-up DNA samples from BM and/or PB of 31 patients (28 IGH and 3 BCL1) were available for MRD analysis. For this report, samples were reanalyzed by highly sensitive, standardized ASO-ddPCR, in addition to previously reported nested PCR results¹⁴.

No significant differences in baseline characteristics of analyzed vs not analyzed patients were observed, except for BM involvement ($p=0.003$, Table S1), as no differences were noted for PFS and OS rates [7 years PFS and OS 40% (95%CI 14-68) vs 59% (95%CI 42-72), $p=0.38$, and 67% (95%CI 34-86 vs 62% (95%CI 46-74), $p=0.95$, respectively].

After two cycles of RBAC500 (REST1), 20/28 patients (71%) scored MRD negative in BM and 23/28 (82%) in the PB. At the end of treatment (REST2), 22/27 (81.5%) scored MRD negative in BM, and 22/26 (85%) in the PB. Of the 20 patients with available follow-up samples at one-year after the end of treatment (REST4), 16 (80%) were still MRD negative in the BM and 18/20 (90%) in the PB. In the following time-points the number of negative patients slightly decreases over time, as showed in Figure 4.

In a landmark analysis starting from response at the end of treatment, MRD negative patients had better, but not significant, outcomes for both PFS and OS than MRD positive patients [7-year PFS 65% (95% CI 42-81) vs 40% (95% CI 5-75), $p=0.148$]; 7-year OS, 65% (95%CI 42-81) vs 40% (95% CI 5-75), $p=0.162$], (Figure 1D, 1E).

Further details on patients' behavior according to MRD analysis at different time-points are showed in the supplements (Figure S2A-S2B and S3A-S3B).

DISCUSSION

We report on the long-term follow-up of the RBAC500 phase 2 trial, showing that this regimen achieved its goal of maintained activity over time, with median PFS and OS figures that were not yet reached after prolonged follow-up. These results, that were achieved without maintenance therapy, support the use of RBAC in elderly patients with MCL, even when judicious dose reductions are implemented in order to avoid hemato-toxicity.

As for previous observations, blastoid/pleomorphic morphology was the most relevant independent predictor of adverse survival. Unfortunately, at the time of the study conception, no study of TP53 function was planned, which limits our knowledge on the activity of R-BAC in TP53 mutated patients, and represents a limitation of this study. Indeed, the FIL VR-BAC trial (NCT03567876), which has completed recruitment approximately one year ago¹⁶, will fill this gap soon.

The results obtained with R-BAC compare favorably with other immuno-chemotherapy regimens (with or without maintenance) in similar populations. The VR-CAP frontline therapy was tested in a randomized trial against R-CHOP¹⁷, showing a median PFS of 24.7 months, but prolonged median OS of 90.7 months. In 2020 Kluin-Nelemans et al. reported on the long-term update of the phase III European Mantle Cell Lymphoma Network Elderly trial, where median OS was 6.4 years. Maintenance therapy with rituximab following response to R-CHOP was associated with a median PFS of 5.4 years¹⁸. In the STIL study

patients treated with BR had a median PFS of three years. Our trial has apparently similar population to that included in the STIL study², with median age of 70 (64.5–74) and 71 (67–75), respectively, but was associated with a 3-years PFS of 76%⁷. Similarly, in the Bright study, median PFS after long-term follow up for the BR arm approximated 48 months¹⁹. A direct comparison between BR and R-BAC has been performed in a real-life study using a propensity score to match patients for characteristics at presentation and reduce selection bias. This study¹⁰ showed that patients treated with R-BAC had 2-year PFS of 87% ± 3% as compared to 64% ± 7% for BR ($p = 0.001$). In terms of toxicity, R-BAC was associated with significantly more pronounced grade 3–4 thrombocytopenia than BR (50% vs. 17%), but the efficacy of R-BAC was preserved when doses were reduced. Overall, the present trial, and real-life experience in patients treated with R-BAC consistently report similar efficacy results, but significantly reduced toxicity, when the regimen is administered at attenuated doses, in a 2-day fashion, or with flat doses of bendamustine and cytarabine (i.e. 100-500 mg total dose, respectively, in 2 consecutive days, skipping the 3rd day of cytarabine)^{7,10}. In clinical practice, after a first cycle we generally administer at full dose, we recommend to adopt similar dose reductions, with patients who are unfit, or older than 75, that may take advantage of the 100-500 regimen.

The SHINE trial¹¹ is a large randomized international trial reporting on the association of ibrutinib, a Bruton's tyrosine kinase inhibitor, in combination with BR, followed by rituximab maintenance, in elderly patients with previously untreated mantle-cell lymphoma. This study established the superiority of the ibrutinib containing arm, together with BR and maintenance rituximab, in terms of PFS in respect to BR plus maintenance but with placebo. With a median follow-up of 84.7 months (very similar to that of the present study), the median PFS in the ibrutinib containing winner arm was 80.6 months, which resembles our observation with the R-BAC regimen, where cytarabine is added to BR instead of ibrutinib, but no maintenance is administered. Overall, the demographic characteristics of the population analyzed in the SHINE trial was comparable to that described in the present study [(median age 71 y for both, advanced Ann Arbor Stage in 89.3% and 91%, high risk MIPI in 35.6% and 31%, respectively, but much higher prevalence of blastoid/pleomorphic variants in RBAC 500 trial (25% vs 7.3%, respectively)]. Seven-years OS was 55% in the ibrutinib group of the SHINE, as compared to 63% in the RBAC500. We acknowledge that comparisons between different studies usually hide pitfalls, but still we describe a PFS curve for R-BAC that is largely similar to the PFS achieved by BR+ibrutinib+maintenance rituximab and ibrutinib in the SHINE trial. Furthermore, the avoidance of maintenance may gain importance in the era of COVID-19, where concern has been raised on infectious complications for patients that are long-term maintained with anti-CD20 antibodies²⁰.

R-BAC was associated with high MRD negativity at the end of induction, with 81.5% of analyzed patients scoring negative in the BM, and 85% in the PB. This percentage is in line with MRD results of intensive chemo-immunotherapy regimens usually offered to younger patients^{21,22}.

The cumulative incidence of SM (including skin cancers) at 7 years in our cohort was 11.2% (95% CI 4.5-21.3), and the median time to SM was 68 months (range 55-91), with three patients (5%) that died during follow-up due to SM. One patient developed secondary leukemia. This is in line with the SHINE study¹¹, where SM (also including skin cancers) were observed in 20.8% and 18.8%, respectively, in the two arms, and 3.8% of deaths were related to SM. In the VR-CAP versus R-CHOP study¹⁷ the reported rate of SM was lower (4.1%, ten patients in each group), and mortality was 1.6%. In younger patients treated with Rituximab-HyperCVAD, a 5% rate of secondary myelodysplasia was reported²³ It is difficult

to drive conclusions on the risk of developing SM according to different regimens, but we acknowledge that this topic deserves specific studies in MCL.

In the present study, OS from the time of progression of disease - POD (OS-2) was 8.9 months. Patients that were refractory to induction therapy or who experienced POD-24, n=25, had significantly inferior 2y OS-2 than patients with late-POD [22% (95% CI 3-51) vs 53% (95% CI 21-78), p=0.02, Figure 3C, confirming observations from others both in younger and elderly patients²⁴⁻²⁶. Indeed, ibrutinib was not available in Italy at the time of relapse for most patients included in this study, and this explains why only a minority of patients were treated at relapse with this compound.

In conclusion, we have reported long-term outcome of elderly patients with MCL treated upfront with R-BAC in the prospective RBAC500 FIL trial. Responses were durable without maintenance therapy, and compared favorably with modern examples of combination therapy. This regimen was not associated to unexpected long-term toxicities. With a median PFS and OS exceeding 50% after 7-years this regimen has significantly impacted on the life-expectancy of elderly patients with MCL, a disease that a couple of decades ago was still associated with a median OS of less than 3 years in similar populations.

Acknowledgements:

We thank all patients who participated in this trial. We thank the Fondazione Italiana Linfomi secretary and particularly Elisa Masiera, Claudia Peracchio and Antonella Ferranti. We thank Emilia Elizbieta Florea and Anna Bordin for scientific and administrative contribution to the work, and AIL section of Verona. We thank Valentina Tabanelli for contributing to the central pathological review. This research was supported by Progetto di Ricerca Sanitaria Finalizzata 2009 grant (RF-2009-1469205) and 2010 grant (RF-2010-2307262); AO S Maurizio, Bolzano/Bozen, Italy; Fondi di Ricerca Locale, Università degli Studi di Torino, Italy; Fondazione Neoplasie Del Sangue, Torino, Italy; and Fondazione Cassa di Risparmio di Torino (project code 2015.1044), Torino, Italy.

Authorship Contributions:

CV and MCT conceived and wrote the paper. All authors were involved in patient recruitment, data collection, and database assembly, and approved the final version of the report. CV, MCT, SFe and AE, analyzed and interpreted the data. SFe and MF analyzed minimal residual disease and SAP performed the central pathological review.
