Abstract: The definition *New psychoactive substances* (NPS) refers to emerging drugs whose chemical structures are similar to other psychoactive compounds but not identical, representing a "legal" alternative to internationally controlled drugs. There are many categories of NPS, such as synthetic cannabinoids, synthetic cathinones, phenylethylamines, piperazines, ketamine derivatives and tryptamines. Tryptamines are naturally occurring compounds, which can derive from the amino acid tryptophan by several biosynthetic pathways: their structure is a combination of a benzene ring and a pyrrole ring, with the addition of a 2-carbon side chain. Tryptamines include serotonin and melatonin as well as other compounds known for their hallucinogenic properties, such as psilocybin in 'Magic mushrooms' and dimethyltryptamine (DMT) in Ayahuasca brews.

Aim: To review the scientific literature regarding tryptamines and their derivatives, providing a summary of all the available information about the structure of these compounds, their effects in relationship with the routes of administration, their pharmacology and toxicity, including articles reporting cases of death related to intake of these substances.

Methods: A comprehensive review of the published scientific literature was performed, using also non peer-reviewed information sources, such as books, government publications and drug user web fora.

Conclusions: Information from Internet and from published scientific literature, organized in the way we proposed in this review, provides an effective tool for specialists facing the emerging NPS threat to public health and public security, including the personnel working in Emergency Department.

Keywords: Clinical effects, Emergency Departments, Fatalities, Forensic Toxicology, Intoxication, New Psychoactive Substances (NPS), Tryptamines.

INTRODUCTION

The *New psychoactive substances* (NPS) are defined by European Community (2005) as "substances of abuse either in a pure form or preparation that are not controlled by the 1961 Single Convention on Narcotics Drugs or the 1971 Convention on Psychotropic Substances, but which may pose a public health threat comparable to scheduled substances" [1]. According to Zuba, "they are created usually by manipulating already existing psychoactive substances or, less, by finding drugs with a new chemical structure that may produce similar effects to those of the illegal drugs of abuse" [2]. They may be formulated as "bulk powders, liquids, tablets, capsules, blotters," or herbal preparations, indeed on the web sites these drugs are sold as "research chemicals," "incense," "bath salts," or "plant-growth fertilizers," equipped with labels specifying that the products are "not for human consumption" or "not for sale to minors" [3]. The International Narcotics Control Board

regards the Internet "as a growing source of on-line drug trafficking": products purchased on Internet may vary over time proposing chemicals always different, not listed in literature, meaning that users are often unaware of what or how much they are taking [4], causing increasing risks to public health. The phenomenon of marketing illicit drug "derivatives" grew mainly because of their easy availability on the Internet or in "head shops". The use of NPS has increased dramatically in recent years: only in the European Union, the number of NPS identified has risen "from 14 at the end of 2005 to 236 by the end of 2012" [5]. The majority of new recreational synthetic drugs fall into one of the following psychoactive drug categories: synthetic cannabinoids, synthetic cathinones, phenylethylamines, piperazines, ketamine derivatives and tryptamines.

Tryptamines are a group of monoamine alkaloids (Fig. 1), which can be synthesized by decarboxylation of the amino acid tryptophan: they can be found in plants, fungi, animals, microbes and amphibia [6].

Tryptamines have an indole ring structure, a fused double ring comprising of a pyrrole ring and a benzene ring, joined to an amino group by 2 carbon side chain.

Fig. (1). Tryptamine structure.

The tryptamines play a fundamental role in human life: serotonin (5-hydroxytryptamine, 5-HT), one of the most important signaling hormones [7] in the body, is a tryptamine natural derivative involved in regulation and modulation of multiple processes within the central nervous system, such as sleep, cognition, memory, temperature regulation and behavior [8]. Moreover, mammalian brain contains very low concentrations (in the low ng/g range) of tryptamine, which may act as a neurotransmitter or modulator [9]: it acts as a serotonin releasing agent and it is an enhancer of serotonergic activity [10]. Gibbons in his publication, defines the nature “an astounding chemist (...) able to produce compounds that have profound effects on the central nervous system (CNS)”[11]. Naturally occurring derivatives of the tryptamines are present in the ‘Magic mushrooms’ belonging to *Psilocybe cubensis* species, which contain psilocybin (4-phosphoryloxy-N,N-dimethyltryptamine) and psilocin (4-hydroxy-N,N-dimethyltryptamine), the latter showing marked similarities with serotonin (Fig. 2).

Another example of the ability of the natural world to create hallucinogenic substances, is the 5-hydroxy-N,N-dimethyltryptamine (bufotenine), a positional isomer of psilocin [12], which is contained in the skin and glands of various species of toad of the genus *Bufo* [13]. Chemical modifications of the nucleus structure of the tryptamine molecule produce new compounds which may cause alterations of the physical and mental status: substitutions on the indole ring, on the two carbons of the side chain and alkylation of the side-chain nitrogen result in new neuroactive compounds, ranging from toxic substances to anti-migraine drugs, such as Sumatriptan [14], Rizatriptan and Zolmitriptan (Fig. 3).

Tryptamines show agonist action at multiple receptors, including 5HT_{2a-1a-2c} [15] serotonin receptors [16], and several ion channels [17]. In general, tryptamines seem to have hallucinogenic properties, rather than stimulant or entactogenic characteristics: their alpha methylation leads to stimulant activity [α -methyltryptamine (AMT), 5-methoxy-

α -methyltryptamine (5-MeO-AMT)], being the presence of an alpha carbon methyl group, a characteristic in common with amphetamine [14, 18]. The synthesis and the effects of these compounds have been fully investigated by Alexander T. Shulgin who described his experiences within the book Tihkal [19]: he identified 55 molecules and he tested these substances on volunteers to assess their effects according to his rating scale. Recreational use of tryptamines requires only minute amounts to produce psychotropic phenomena and has been associated to intoxications and fatalities for several reasons, including low toxic concentrations. Moreover, these molecules are not routinely detected with common screening panels, so far in emergency rooms the test could result completely negative leading to misunderstanding diagnosis or therapy and limited evaluation of the phenomenon. It is very important to organize the information pertaining to these substances to provide a tool for specialists facing this emerging threat to public health and public security. For this reason a comprehensive review of the scientific literature and internet sites regarding tryptamines and their derivatives was carried out, providing a summary of all the available information about the structure of these compounds, their effects in relationship with the routes of administration and their toxicity, including articles reporting cases of death related to intake of these substances and analytical methods for the determination and quantification of some tryptamines.

CLASSIFICATION OF TRYPTAMINES BASED ON THEIR CHEMICAL STRUCTURES

Several classifications have been suggested for these substances. Nichols classified tryptamines in two main groups: -the simple tryptamines, including dimethyltryptamine (DMT), and the ergolines (a group of chemical compounds that were originally synthesized from a fungus ergot, among which is the lysergic acid diethylamide (LSD)). Fantegrossi divided tryptamines in three subgroups: (1) simple tryptamines, without modification of the indole ring; (2) tryptamines having a modification on the 4-position on the indole ring; (3) tryptamines having a modification on the 5-position. Only

substitutions on the 4-5 positions were considered because changes in position 6 or 7 result in reduced hallucinogenic activity [14] (Fig. 4).

STRUCTURE-ACTIVITY RELATIONSHIPS IN TRYPTAMINES AND THEIR METABOLISM

The effects caused by the administration of tryptamines are closely related to their structures, as each of these compounds has a different receptor affinity to which are related psychoactive phenomena.

RING UNSUBSTITUTED COMPOUNDS

Several compounds belong to this class, including α -methyltryptamine (AMT, street name Spirals) and α -ethyltryptamine (AET) both showing stimulant activities [18].

Alpha-methyltryptamine (AMT) was firstly developed as an antidepressant agent called as INDOPAN, in 1960's by the Upjohn Company and used for a short period of time in the former Soviet Union [20], but at last it was recognized as a toxic substance able to produce psychosis [21].

AMT activity is linked with the release of dopamine and its re-uptake inhibition. AMT also acts on serotonin and noradrenaline receptors and inhibits MAO activity *in vitro* and *in vivo*, therefore it is active after oral administration. Nagai [16] in his study, developed a method to determine the reuptake and release of monoamines (dopamine, serotonin and norepinephrine), and "analyzed the effects of various

designer drugs on monoamine neurotransmission", using rat brain synaptosomes. He disclosed that AMT presented the "strongest monoamine re-uptake inhibitory activity and release stimulating activity, although monoamine release was more dominant than re-uptake inhibition" [16]. Furthermore, he discovered that 5-MeO-AMT, "inhibited monoamine (dopamine, 5-HT and norepinephrine) re-uptake and stimulated monoamine release; its potency was second to that of AMT. AMT and 5-MeO-AMT both have a primary amine group, which in tryptamine might be indispensable for the stimulation of monoamine release" [16]. Illegal use of α -methyl-tryptamine is based on its hallucinogenic and psychedelic visual effects, with doses ranging from 15 to 30 mg if administered orally. It can be smoked (4-20 mg) as freebase, and snorted as well. The onset of action, if orally administered, is between 3 and 4 hours, generally lasting up to 12-24 hours, but in some subjects the action can last until 2 days. The onset of action if smoked is in the range of seconds or minutes. Uncomfortable feelings are reported, such as restlessness and irritability, hyperthermia, anorexia, vomiting, inability to sleep, tachycardia, increase in blood pressure pupils dilatation, deep tendon reflexes and coordination impairment [22]. Wilcox [23] interviewed 15 individuals who had used α -methyltryptamine. Most common side effects reported were anxiety, nausea and moderately severe dysphoria as well as depression (15% severely depressed mood on the day after). The 90% of patients reported visual hallucinations and 87 % euphoria. Anxiety was lamented in 35% of cases, in a correlation with crowded environment. AMT, as every psychedelic agent can alter judgement and

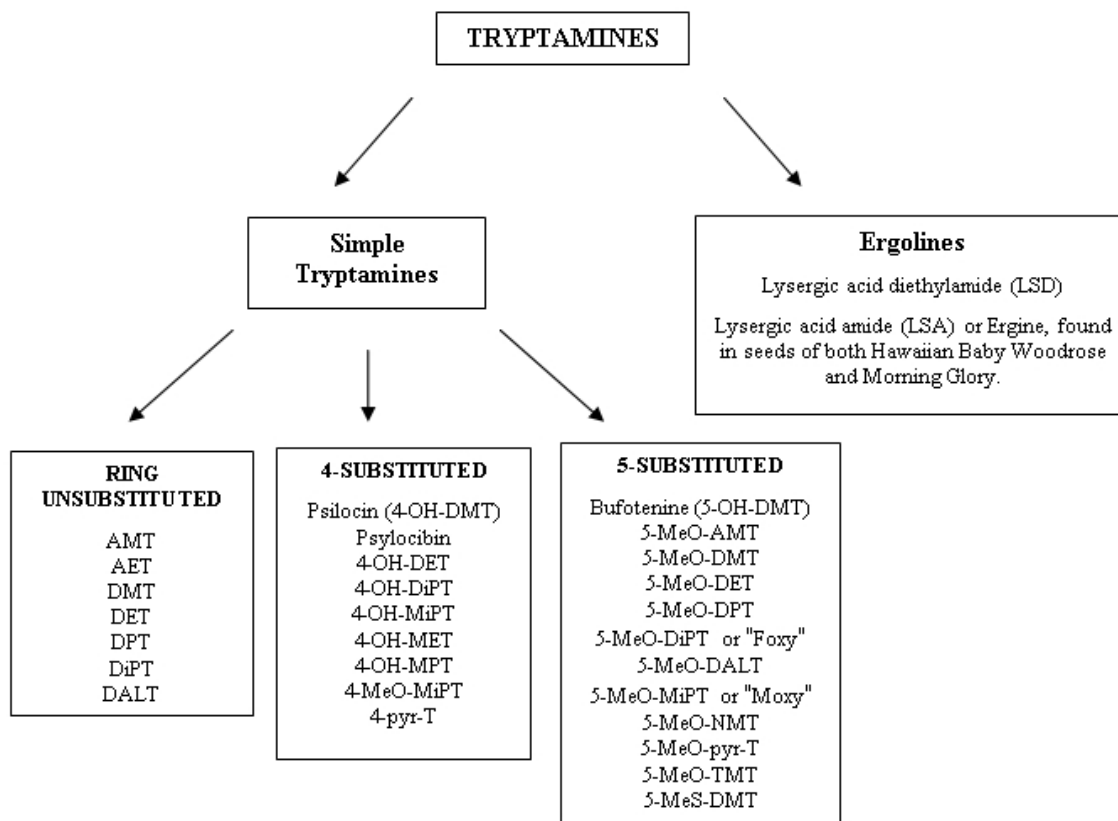

Fig. (4). Classification of tryptamines.

perception and therefore it can cause dangerous behaviours. In the US, since 2004, it's placed as a schedule I substance, while in the UK it was completely legal until June 2014 [24]. According to the NPSAD (National Program on Substance Deaths Abuse) Annual Report, from January to December 2012 in the UK, α -methyltryptamine has showed the highest number of deaths (2 reported in 2011 and 4 reported in 2012) compared to tryptamine or 5-methoxy-diallyltryptamine (5-MeO-DALT) [25].

Also **alpha-ethyltryptamine** (AET) was firstly introduced as an antidepressant agent by Upjohn company in 1960s with the name MONASE, but it was withdrawn from the market because of an unacceptable incidence of idiosyncratic agranulocytosis. AET may induce serotonin neurotoxicity [26], similar to that of MDMA and para-chloroamphetamine (PCA), as reported in studies on rats. AET inhibits MAO activity [27] *in vitro* and *in vivo*, as AMT, and it is orally active. Lessins [18] studied the effects of these two alpha-tryptamine derivatives in mice, observing marked stimulation with increased locomotor activity, hyperthermia, midriasis and generalized body tremor: AET assumption is also correlated with psychedelic, stimulant, and entactogenic effects.

The dosage reported by Shulgin, for oral administration, is 100-150 mg. and it seems to be able to fight opiate addiction in anecdotal reports. "It appears to serve well, with short term dosage regimens, as an effective tool in kicking dependency on opiates" [19].

Dimethyl-tryptamine (DMT) was first synthesized in 1931 by Richard Helmuth Fredrick Manske, but it was discovered as a natural product only in 1946, when a Brazilian chemist and microbiologist, Oswaldo Gonçalves de Lima, isolated it from the root bark of *Mimosa tenuiflora*. Since 1955 DMT has been found in at least fifty species of plants belonging to ten families [28], in four species of animals, and in three species of mammals. The biosynthesis of DMT begins with the decarboxylation of tryptophan that leads to the production of tryptamine. Further, tryptamine undergoes a methylation process, generating the intermediate product N-methyltryptamine (NMT). NMT is in turn transmethylated to form the final product N,N-dimethyl tryptamine. DMT binds several serotonin receptors, acting as a partial agonist in particular on the 5-HT_{2A} and 5-HT_{2C} receptors. It has also been shown to possess affinity for the α_1 and α_2 -adrenergic receptors, dopamine D₁, and sigma-1 (σ_1). The psychedelic activity of DMT, similar to LSD and mescaline, can probably be attributed to the binding to 5-HT_{2A} receptor, although the activation of other receptors, such as 5-HT_{2C} and sigma-1, may play a very important role in the onset of these effects [29]. DMT can be taken orally, intravenously or by inhalation. When inhaled, a standard dose of DMT is 15–60 mg. The onset of the effects is very fast, less than 45 seconds, peak effects are reached within a minute and they last usually for about 15 minutes. The experiences after injecting a DMT are similar to inhalation in duration, intensity and characteristics. If orally administered DMT must be associated with a MAOI, as it is deaminated by monoamine oxidase and is quickly inactivated. The Ayahuasca brew, used in religious rituals of the native

peoples of the Amazon, is obtained by boiling the Ayahuasca vine (*Banisteriopsis caapi*), that contains monoamine oxidase inhibitors (β -carbolines harmaline, harmine, and 1,2,3,4 tetrahydroharmine) with the leaves of shrubs of the genus *Psychotria* or *Diplopterys*, that contains DMT. A review on the risk assessment of the use of Ayahuasca has been made by Gable, who reported that to achieve the lethal dose in humans, it would be necessary to ingest more than 20 times the ceremonial dose. The brew seems also to have minimal dependence potential [30].

Diethyl-tryptamine (DET) has not been found to occur naturally and, although presenting structural similarity to DMT, it is active when administered orally, due to the presence of two ethyl groups linked to its nitrogen atom, preventing its degradation by MAO. Its mechanism of action is not clear, but, like other psychedelic tryptamines, DET could present an agonist activity towards serotonin receptors [31, 32]. When orally administered the dosage is 50–100 mg and the effects are reported to last about 2–4 hours [33].

Dipropyl-tryptamine (DPT) was firstly synthesized in the 1950s [34], but it was firstly reported for use in the scientific literature only in 1973 [35], as an adjunct in psychotherapy of alcoholics. It is found either as its crystalline hydrochloride salt or as an oily or crystalline base and, as DET, it has not been found to occur naturally. There are few peer-reviewed experimental studies that try to explain the ways of interaction among DPT and serotonin receptors: Nagai revealed a strong inhibition of 5-HT reuptake in rat synaptosomes [16], and Thiagaraj also observed a moderate affinity partial agonism at the human 5-HT_{1A} receptor [34]. Experiences related to DPT assumption are mostly psychedelic sensations, such as an increase of music and colors intensity, the vision of pleasant flashes of light and sparkles, a complete ego loss, and apparitions of faces. The dosage of DPT, for oral administration, is 100-250 mg and the duration of the psychoactive effects varies from 2 to 4 hours.

Diisopropyl-tryptamine (DiPT) is a synthetic hallucinogen, structurally related to dimethyl-tryptamine, but, unlike DMT, which produces short term visual hallucinations, DiPT causes auditory distortions [36]. DiPT presents a similar molecular mechanism of action as other hallucinogens. It is an agonist at 5HT_{2A} receptors and a partial agonist at 5HT_{1A} receptors [37], but 5-HT_{1A} activity "is not thought to be necessary for hallucinogenic effects" [38]. Furthermore, DiPT blocks the serotonin uptake and it has little interaction with dopamine or norepinephrine transporters [16].

Effective dosage, orally administered, ranges from 50 to 100 mg [39] and the hallucinogenic effects continue until 6-8 hours.

4-POSITION MODIFIED TRYPTAMINES

Psilocin (4-OH-DMT) can be assumed "as the prototypical agent of the 4-position modified tryptamines" [15]. It is obtained by dephosphorylation in the body of **psilocybin** found in hallucinogenic mushrooms of the species *Psilocybe* and *Stropharia*. In *P. cubensis*, psilocybin percentage varies

from 0.2% to 0.4% of the dry weight [40], while psilocin is only present in trace amounts. After ingestion, psilocybin undergoes rapid hydrolysis of the phosphate groups by the alkaline phosphatase and then turns into its active metabolite psilocin, representing the active drug of abuse [41]. After the ingestion of *Psilocybe* 'Magic mushrooms', the hallucinogenic effects arise within the first 2 hours and then decrease in the subsequent 3-4 hours to disappear within 4-8 hours. The threshold of intoxication is reached after the intake of 40 µg psilocybin/kg body weight; "typically 1-2 g of dried mushroom is ingested", which yields from 2 to 8 mg of psilocybin [42]. "Pharmacokinetic studies of psilocybin in humans have shown" that, after "the rapid dephosphorylation of psilocybin to psilocin", there is a conversion in plasma of "the psilocin into 4-hydroxy-tryptophole (4HT) and 4-hydroxyindole-3-acetic acid (4HIAA)" [43]. Grieshaber showed that psilocin undergoes conjugation with glucuronic acid in the liver and it can be found in the urine as the psilocin-glucuronide conjugate [43]. Psilocin is a partial 5HT_{2a} agonist [14], but it is also agonistic at other serotonin receptors, with little dopaminergic or noradrenergic action: these activities explain the onset of sympathetic stimulations, such as tachycardia and hypertension, along with those of the predominant hallucinogenic effects [44]. Psilocybin is orally active, with effective doses in the range of 6-20 mg. The onset of action is typically 20-40 min, peaked after another 60-90 min, lasting for another 60-120 min [45].

The synthetic 4-substituted tryptamines include **4-hydroxy-N,N-diethyltryptamine** (4-HO-DET), **4-hydroxy-N,N-diisopropyltryptamine** (4-HO-DiPT), **4-hydroxy-N-isopropyl,N-methyltryptamine** (4-HO-MiPT) and their acetic acid derivatives (for example, **4-acetoxy-N,N-diethyltryptamine** and **4-acetoxy-N,N-diisopropyltryptamine**): all these compounds, according to users [46], seem to have similar actions to psilocin, but very little scientific information about their properties is available.

5 POSITION MODIFIED TRYPTAMINES

Bufotenine (Fig. 5), or 5-OH-dimethyltryptamine (5-OH-DMT), is an N-alkylated derivative of serotonin and it was first synthesized by Wieland in 1934 [47]: it can be isolated from plants *Piptadenia peregrina* and *P. macrocarpa* (Mimosaceae), the mushrooms *Amanita* (spp) and from the skin glands of toads (*Bufo* spp.) [48]. Fuller, studying the metabolism, the tissue distribution and the effects of 5-OH-DMT on rats, showed that, after injection in the animals, it was present in highest concentration in lung and in heart rather than in brain: this, probably, means that it does not cross well the blood-brain barrier, just as serotonin [49]. In tissues studies, he found that bufotenine was rapidly

BUFOTENINE

Fig. (5). 5-hydroxy-N,N-dimethyltryptamine.

eliminated, disappearing within 8 hours, after reaching peak concentrations at 1 hour. Moreover, the large increases of 5-hydroxyindoleacetic acid (5HIAA), the endogenous metabolite of serotonin, in all tissues suggested that bufotenine was metabolized by MAO-A through the pathway of oxidative deamination.

Ott, published the results of his human self-experiments with bufotenine: he self administered bufotenine as free base, *via* intranasal (5-100 mg), sublingually (50 mg), intrarectally (30 mg), pulmonary (as inhaled vapor, in a dosage of 2-8 mg) and orally (100 mg). These experiments were done by way of "pharmacological modeling of diverse South American shamanic inebriants, prepared from seeds of *Anadenanthera peregrina* and *Anadenanthera colubrina*". For each route of self-administration, Ott reported the onset of several psychoactive effects, in relation to the dosage.

Intranasal administration (nine bioassays from 5 to 100 mg): he reported the visionary threshold at 40 mg; the range from 5 to 30 mg caused the onset of psychoactive effects at all doses, "with closed-eye luminosity and scintillation commencing at 20 mg". He recorded that at 5 minutes after the 40 mg administration, he felt the onset of tinnitus; at 25 minutes he felt the body effects typical of the intakes of tryptamines; the peak arrived between 35 and 40 minutes and all the psychoactive sensations vanished after 90 minutes. He noted also that he did not feel discomfort or side-effect.

Sublingual administration (50 mg): he reported that "free base bufotenin taken sublingually was found to be similar to intranasal use", for what concerned "the potency, duration, and psychedelic action".

Intrarectal administration (30 mg): he reported mild physical effects that developed quickly and that lasted roughly an hour. He felt psychotropic effects, like scintillations with closed eyes, only when he co-administered harmaline with bufotenine suppository.

Administration via inhaling vapor (2-8 mg): he inhaled 2, 4, 6 and 8 mg of bufotenine. All doses were decidedly psychoactives, increasing in potency proportionally to dosage. The peaks were attained after four to five minutes with a gradual diminution of the effects for an hour.

Oral administration (100 mg): he reported that 100 mg dose was most decidedly psychoactive. Tinnitus manifested at 20 minutes, the peak was reached at one hour and 30 minutes "with all the classic tryptaminic bodily sensations and mild psychoptic effects, but absent colored patterns" [50].

The 5-substituted tryptamines, also include 5-methoxy- α -methyltryptamine (5-MeO-AMT), 5-methoxy-N,N-dimethyltryptamine (5-MeO-DMT), 5-methoxy-N,N-diisopropyltryptamine (5-MeO-DiPT, "Foxy Methoxy"), 5-methoxy-N,N-methylisopropyltryptamine (5-MeO-MiPT): these compounds inhibit monoamine re-uptake, but they have few effects on monoamine release.

5-methoxy- α -methyltryptamine (5-MeO-AMT) is a psychedelic tryptamine which presents structural similarities

to the amphetamines: because of these characteristics, 5-MeO-AMT was occasionally sold under the guise of LSD, as emerges from the reports of Drug Enforcement Agency (DEA) about seizures of sugar cube, or blotters LSD-style, containing this tryptamine [51]. Its mechanism of action is characterized by binding to 5-HT_{1A} and 5-HT_{2A} receptors [52, 53] it also inhibits the monoamines reuptake and increases their release in brain synaptosomes at micromolar concentrations [16]. 5-MeO-AMT is orally administered in a range of 2.5-4.5 mg and the duration of the effects reported is about 12-18 hours. If misrepresented as LSD, 5-MeO-AMT can be very harmful or even fatal: in fact, incorrect or excessive administration of the substance, mistaken for LSD, has been the cause of several hospital admissions [54] or sudden deaths [55].

It is likely that the danger related to 5-MeO-AMT assumption is due to its sympathomimetic effects, that include, as side effects, cardiac arrhythmia and seizure.

5-methoxy-N,N-dimethyltryptamine (5-MeO-DMT) is a naturally occurring psychoactive indolealkylamine substance, closely related to DMT and bufotenine. It was initially isolated from the bark of *Dictyoloma incanescens* [56], but it was found also in the venom of Colorado River *Bufo alvarius*, secreted by parotid and tibial glands. This compound is a potent, fast acting hallucinogen [57], producing psychedelic effects, with a short duration in humans: it has high affinity for the 5-HT_{1A} serotonin receptor, causing many physiological and behavioral changes. It can be administered by different routes, as reported in the Table 1.

Table 1. Routes and dosages of administration of 5-MeO-DMT in humans from Shen [57].

5-MeO-DMT	
Routes of Administration	Dosage (mg)
Inhalation	6 - 20
Intravenous injection	0.7 - 3.1
Sublingual or Intranasal insufflation	10
Oral (with MAOI)	30

5-MeO-DMT is mainly metabolized by monoamine oxidase A (MAO-A) through a deamination pathway, and it is *O*-demethylated by cytochrome P450 (CYP2D6) enzyme [57], producing, as active metabolite, bufotenine, which binds 5-HT_{2A} receptor with higher affinity than 5-MeO-DMT itself.

For this reason, to produce a prolonged hallucinogen effect when orally administered, 5-MeO-DMT requires the concomitant use of a MAOI, such as harmaline. This co-administration could lead to an hyperserotonergic syndrome because of the agonistic activity of these two substances on the serotonergic system: in fact, MAOI activity causes an increasing exposure to the parent drug (5-MeO-DMT) and to

the active metabolite (bufotenine), originating a possible fatal toxicity (Fig. 6).

In his self-experiments, Ott, revealed that after insufflation [58], 5-MeO-DMT caused visionary and auditory changes, with a distortion of the perception of time. The onset of these effects was after 3-4 minutes from the administration, the peak was reached after about 35-40 minutes and they lasting until 60-70 minutes. He demonstrated also that oral ingestion compared with intranasal or sublingual ingestion of 30-35 mg of 5-MeO-DMT produced limited effects or could produce no psychoactive effects at all.

5-methoxy-diisopropyltryptamine (5-MeO-DiPT), or "Foxy Methoxy", produced by the addition of two isopropyl groups to the terminal nitrogen of the aminoethyl group, and methoxylation of the 5-position of the indole ring, is a synthetic designer drug which was first synthesized and described by Shulgin.

Sogawa "investigated the actions of 5-MeO-DiPT against monoamine neurotransmitter transporters, using COS-7 cells heterologously expressing these transporters and rat brain synaptosomes", and demonstrated that "5-MeO-DiPT acts as a competitive serotonin transporter (SERT) inhibitor and has an inability to cause reverse transport, underlying its serotonergic actions" [59]. Agonistic activity at serotonin receptors could lead to permanent damages to serotonergic neurons with neuropsychiatric implications [60]. Fantegrossi reported also that "5-MeO-DiPT had affinity for receptors relevant to hallucinogenic effects" observed *in vivo*, and that the psychotropic activity of 5-MeO-DiPT might therefore be caused by its association with post-synaptic 5-HT receptors [61]. In human biological samples, such as blood and urine, 5-MeO-DiPT is mainly metabolized in 5-hydroxy-N,N-diisopropyltryptamine (5-OH-DiPT) and in 5-methoxy-N-isopropyltryptamine (5-MeO-NiPT) [62]. 5-MeO-DiPT is orally active, and dosages between 6-12 mg are reported by Shulgin, but it can be also smoked, or snorted. Its onset of action is in 20 to 30 minutes, and its effects last from 3 to 6 hours. The users experienced euphoria, disinhibition, increased sociability, visual and auditory hallucinations, feeling of love but also less desirable effects like myoclonus, restlessness, insomnia and anxiety, as well as emotional distress like nausea, vomiting and diarrhea.

5-methoxy-N,N-diallyltryptamine (5-MeO-DALT) was first synthesized by Shulgin and although information on this tryptamine was available since 2004, "its use as hallucinogenic drug has been reported only occasionally in on-line fora" [10]. According to the European Database on New Drugs (EDND), it was first sequestered as two grey tablets, in 2006 at Helsinki airport [10]. There is little scientific literature on this tryptamine: Nonaka showed that 5-MeO-DALT seemed to support G protein activation *via* serotonin 5-HT₁ receptor with experiments on rat brains [63]. Moreover, it did not show effect on dopamine, serotonin and norepinephrine re-uptake and presented a slight monoamine-releasing activity [16]. 5-MeO-DALT is mainly found in powder form that is taken orally or nasally. The range of doses and effects is unusually broad. Shulgin reported dosages for oral administration from 12 to 25 mg: users

Fig. (6). Agonistic action of harmaline, 5-MeO-DMT and bufotenine on serotonergic system inducing hyperserotonergic effects.

reported that the onset of its effects was within 15 minutes, the peak was reached in 30 minutes and the main effects lasted for 2-4 hours, including euphoria, visual hallucinations, walking difficulties, and 'out of body' experiences.

5-methoxy-N-methyl-N-isopropyltryptamine (5-MeO-MiPT) is an analogue of the more popular drug 5-MeO-DiPT ("Foxy") and, for this reason, it is nicknamed "Moxy".

With regard to its mechanism of action, Fantegrossi demonstrated that 5-MeO-MiPT, as the 5-MeO-DiPT, suppressed the re-uptake of 5-HT and the re-uptake of dopamine and norepinephrine. It showed little dopamine, 5-HT or norepinephrine releasing activity [61].

5-MeO-MiPT can be smoked or orally administered. The dosage for oral use is from 4 to 6 mg and the duration of the effects is from 4 to 6 hours, while if it is smoked the dosage is 12-20 mg. The onset of the psychoactive sensations, after oral assumption, is from 15 to 20 minutes, the peak is reached from 45 to 60 minutes and the return to normality is registered after about 10 hours. If it is smoked, the onset is immediate, the duration of the effects is from 2 to 5 hours and symptoms disappear after about 2-4 hours. The effects reported by the users including euphoria, increased tactile sensations, relaxation, visual distortions and difficulty in sleeping [64].

ERGOLINES: HAWAIIAN BABY WOODROSE AND MORNING GLORY SEEDS

Ergine, or lysergic acid amide (LSA), is an alkaloid of the ergoline family closely related to LSD, found in the seeds of *Argyreia nervosa* (Hawaiian baby woodrose) and *Ipomoea violacea* (Morning Glories).

Hallucinogenic activity of LSA occurs with 4-10 seeds of *Argyreia nervosa* or with 150-200 seeds (3-6 g) of *Ipomoea violacea*: seeds could be crushed or eaten whole, or also drunk as an extract, after soaking in water [42]. The onset of

the hallucinatory effects, after ingestion of Hawaiian Baby Woodrose, is from 20 to 40 minutes and their total duration is from 5 to 8 hours: the plateau is reached after 4-6 hours and the return to normality is after 1-2 hours from the plateau. The principal sensations reported by the users include relaxations, mild euphoria, feelings similar to alcohol intoxication [65], psychedelic visual effects such as enhanced colors, but also anxiety, nausea, confusion and paranoia [66]. However, as regards to the assumption of the Morning Glory seeds, the onset of the hallucinatory effects is from 30 to 180 minutes and they last for 4 to 10 hours. The users reported that they return to normality after about 24 hours [67].

Morning Glory seeds assumption can produce a heightened sense of awareness of colors, textures and sounds: the users reported also a diminished sense of reality, an increased sense of suggestibility, but also a sense of anxiety and panic, nausea, vomiting, and psychotic episodes [68].

EFFECTS DUE TO ASSUMPTION OF TRYPTAMINES REPORTED ON INTERNET

The information regarding the effects of tryptamines reported in this paragraph, is collected from websites, so these effects are exclusively the result of personal experiences of authors and do not follow the use of the scientific method. They are reported because Internet is probably one of the most effective sources of timely information for any specialist or organization interested in the subject.

The tryptamines users are not always aware of what they have purchased and of its chemical constituents, and there are many risks associated with the possibility of overdose, repeated administration and incorrect route of administration. In this section, we are going to report the main effects connected with the use of tryptamines, included the one reported as "positive" by authors.

The routes of administration of the various tryptamines are one of the key factors that need to be evaluated: some can be taken orally or intramuscularly or intravenously, or can be smoked or inhaled, showing an increased of hallucinogenic sensations, especially in relation to dose and repeated-dose toxicity due to a delayed onset of phenomenology.

ASSUMPTION OF RING UNSUBSTITUTED COMPOUNDS

Ring unsubstituted compounds such as α -methyltryptamine (AMT) and α -ethyltryptamine (AET) have stimulant properties

as well as hallucinatory effects [18]. AET is described as having psychoactive properties similar to MDMA. Tables 2 and 3 summarize AMT and AET experiences as reported on www.erowid.org [69, 70].

N,N-dimethyltryptamine (DMT), offers an insight into the psychoactive properties of other tryptamines: it is not active after oral ingestion due to extensive first pass metabolism *via* MAO, so it is generally assumed intramuscularly, subcutaneously, intravenously, or even be smoked. In Table 4 are summarized DMT experiences in relationship with the route of administration reported on the website www.erowid.org [71].

Table 2. The principal routes of administration of AMT and its correlated experiences as reported on www.erowid.org [69].

AMT EXPERIENCES		
Route of Administration	Dosage	Effects (12-16 Hours)
Oral (15-30 mg)	with 15 mg	"I got a strong psychedelic experience that lasted about twelve hours, but an unexpected relief from my chronic depression that lasted for four days."
	with 30 mg	"It felt a little like speed, strong speed. Yet I found myself yawning and in sort of a dreaminess state and quite lethargic. It lasted a long time."
	with 100 mg	"There was pupillary dilation, jaw clenching, tachycardia and vomiting. Too much. But I really liked this compound at lower dosages."
Smoked (5-20 mg)	with 5 mg	"Qualitatively it was milder and less intense than mushrooms, but much longer lived. Not complex, but just a lot of very good spirit, energetic feeling, enhanced colors, attractive rhythms in music. Party stuff."
	with 20 mg	"I inhaled several hits from my vaporizer and sat back. I felt head-pressure and uneasiness, then suddenly I became very fast. My mind was moving fast, and my body was speeding along with it in an unconscious way. Several hours into it, I began to notice more of a psychedelic effect beginning to manifest. It seemed as if the speedy part was becoming less predominant and the psychedelic visual effects were starting to kick in. I went back to my room to watch the distinctive waves of a soft red/orange visuals They were similar to colors of LSD. It gradually increased to a level of intensity, and after several more hours it was clear that I had reached the plateau. Feeling fairly tired and ready for bed, I decided to call it a night. Quite to my surprise, when I awoke four hours later I was at the same level as when I went to sleep. Gradually over the next day I returned to baseline and I was left feeling quite euphoric with a pleasant afterglow."

Table 3. AET experiences at different dosages after oral administration as reported on www.erowid.org [70].

AET EXPERIENCES		
Route of Administration	Dosage	Effects (6-8 Hours)
Oral (100-150 mg)	with 100 mg	"A nearly imperceptible feeling of well-being and pleasure was noted about 80 minutes later, and seemed completely gone at three hours."
	with 150 mg	"My dosage level was the highest of the group, but to my surprise, it had almost no effect whatsoever. A plus-one, if anything. After the peak, as I was slowly coming down, I was aware of feeling slightly depressed. This state continued until I achieved baseline, but was not severe enough to prevent me from participating in the general good spirits of the group. There is a real possibility that my weekly use of MDMA for writing might have built up a tolerance to the stimulation of this material. I think that that may be close to the answer. Would I take it again? Not with much enthusiasm. It didn't give enough exciting rewards."
	with 160 mg	"A strong feeling of being-at-peace was evident in an hour, although there was some concentration required to do things in a coordinated way. I wouldn't want to drive a car. There seemed to be very easy drifting of thoughts but no visuals or sensory distortions. There were no GI disturbances anywhere along the line except for some loose stools the next morning. Appetite was slightly depressed, but food tasted very good. A very slight tremor could be detected in the fingers around the peak of the experience. There was a desire to talk with friends somewhat reminiscent of MDMA; I am sure that this drug could be quite a social-enhancing material. The effects wore off gradually and were essentially gone by the six hour point. Sleep was unaffected, however the next morning there was a slight feeling of dullness and possibly hang-over which quickly wore off."

Table 4. Routes of administration of DMT and its principal psychoactive experiences as reported on www.erowid.org [71].

DMT EXPERIENCES		
Route of Administration	Dosage	Effects (up to 1 Hour)
Oral (>350 mg)	up to 350 mg	"Completely without effect either physiological or psychological"
Intramuscularly (60-100 mg)	with 80 mg	"My perceptual distortions were visual in nature and with my eyes closed I could see colored patterns, primarily geometrical patterns moving very fast, having sometimes very deep emotional content and connotation. My blood pressure went up and my pupils were dilated."
Subcutaneously (60-100 mg) (via the buccal mucosa)	with 100 mg	"Numbness at the site, but no central effects."
Intravenously (4-30 mg)	with 30 mg	"I was hit harder than I had ever been when smoking the stuff. The onset was similar, but the euphoria was less."
Smoked (60-100 mg)	with 100 mg	"As I exhaled I became terribly afraid, my heart very rapid and strong, palms sweating. A terrible sense of dread and doom filled me - I knew what was happening, I knew I couldn't stop it, but it was so devastating; I was being destroyed - all that was familiar, all reference points, all identity - all viciously shattered in a few seconds. I couldn't even mourn the loss - there was no one left to do the mourning. Up, up, out, out, eyes closed, I am at the speed of light, expanding, expanding, expanding, faster and faster until I have become so large that I no longer exist - my speed is so great that everything has come to a stop - here I gaze upon the entire universe."

DMT produces, in recreational doses, sudden onset of intense visual hallucinations [19, 72, 73]. Sympathomimetic effects such as dilated pupils, tachycardia and hypertension are more prominent at lower doses: some users report that the experience is more intense than that following LSD exposure [15].

Unlike DMT, other unsubstituted tryptamines are orally active. Smoking and nasal insufflations are also common

methods of administration. Visual hallucinations are universal reported as "positive" effects by users [74]. General effects reported as "positive" on www.erowid.org by users of unsubstituted tryptamines, that are active after ingestion, include: 'rushing' sensation, both opened and closed eyes 'pleasant' visual hallucinations, increased mood, energy, libido, concentration and empathogenic qualities [75]. These effects are collected in Table 5.

Table 5. Unsubstituted simple tryptamines effects as reported on www.erowid.org [75].

Unsubstituted Tryptamine	Dosage (mg)	Duration of Action (Oral Administration)	"Positive" Effects
DET (N,N-diethyltryptamine)	50-100	2-4 hours	With 44 mg: "I was in a public place, and might have had to interact with someone at any moment, which probably accounted for a grim paranoia and wish to retreat. I had my full effect in just over an hour, with almost no visual or physical properties, but a crashing fear of interacting. Good sleep, no residues." With 150 mg: "There was a slow onset. It was more than an hour before something started. I was heading toward an appointment, and walked right past the meeting place. I was unable to concentrate on just where I was and where I was hoping to go. With enormous effort I located my appointment coordinates but the sidewalk was doing funny things and I again managed to miss my target. I sat down to try to manage things, but I couldn't."
DPT (N,N-dipropyltryptamine)	100-250	2-4 hours	With 200 mg: "This started sooner and was a lot stronger than I had expected. I had trouble talking and I felt very uncomfortable. I think physically I was in a chair but I was on a kind of mountain surrounded by clouds. And the clouds talked to me."
DiPT (N,N-diisopropyltryptamine)	25-100	6-8 hours	With 50 mg: "Everything was auditory, and I can only describe it with a '!" With 100 mg: "Nothing until 35 minutes when a definite change in hearing was observed. There was a decrease in high frequency acuity with an unusual tonal shift of all frequencies to a lower pitch. Voices sounded very similar to a single side-band radio signal which had been mistuned to the low side of the center frequency. No effects were noted with respect to clarity of speech, and both comprehension and interpretation were normal. There were no changes in vision, taste, smell, appetite, vital signs, or motor coordination. The effects began to fade at four hours post ingestion, and were completely gone at eight hours."

ASSUMPTION OF 4-POSITION MODIFIED TRYPYPTAMINES

Synthetic 4-substituted tryptamines are orally active and they seem to produce similar effects to those mediated by psilocin. General effects include: increased laughing, intense visual hallucinations, 'rushing' sensation, euphoria, increased libido, enhanced tactile sensations, increased concentration and a feeling of warmth and inner peace [76]. Dosage and effects of most common synthetic 4-substituted tryptamines on www.erowid.org, are reported in Table 6 [75].

ASSUMPTION OF 5-POSITION MODIFIED TRYPYPTAMINES

The 5-substituted tryptamines are more powerful than the unsubstituted molecules, but clinical effects reported are similar among them. Effects reported as "positive" by users of 5-substituted tryptamines include [58]: euphoria, an increasing of energy, libido, concentration and sociability, and a reduction in fear and anxiety [57]. Table 7 represents a summary of the reported effects of the personal experiences of the users of some 5-substituted simple tryptamines by Alexander and Ann Shulgin [75].

Internet drug user fora, including Erowid, published also reports of the adverse effects following to tryptamine administration. The accuracy of reports is limited by possible user bias, difficulty in ascertaining the identity and amount of the substance exposure and the possibility of co-ingestants. General user reports of adverse or unwanted effects of unsubstituted tryptamines include: restlessness, yawning, anxiety, tension, nausea, vomiting, palpitations, muscle pain, bruxism, headache, frightening or distressing hallucinations, overwhelming fear (DMT), abdominal discomfort, nasal irritation when insufflated and respiratory discomfort or distress when inhaled [76, 78]. Moreover, the incorrect or excessive administration of 5-MeO-AMT, mistaken for LSD, has been correlated with several hospital admissions [54] or sudden deaths [55]. In the Table 8 are summarized the main adverse effects reported by users in relationship with the tryptamine derivatives assumed.

TRYPYPTAMINES EFFECTS AND INTOXICATIONS: CASE REPORTS FROM EMERGENCY ROOMS AND CORONERS' ACTIVITIES

Gathering data on the use of these new psychoactive substances it is very difficult, since they are not collected in a systematic way and often these information come from unverified sources (drug-related fora or websites). So the only evidences that have an epidemiological significance derive from arrests and seizures by law enforcement agencies [14], from the numbers of enquires to poisons centers, from the reports of the emergency departments or from admissions to hospital. Unfortunately, the limited number of these official reports may underestimate the true extent of the problem [80]: statistics on deaths may also be available, but often these publications do not provide information on toxicity or mode of action of these substances as completely lacks the analytical confirmation of the agents involved, and the causes of death are ascertained or through the testimonies of family members and friends, or after the discovery of the substance at home or in the clothes of the

deceased. Nevertheless, in scientific literature are reported a consistent number of cases of acute poisoning due to the increasingly widespread use of these new psychoactive substances: many of these are the result of emergency room experience. As the amount of tryptamines necessary to cause psychotropic effects is minimal, and the interval of occurrence of effects is rather delayed [39], there is a risk of inappropriate new assumptions, that could lead to poisoning or overdose.

Holstege reported the case of poisoning of a college student (male, 21 years old) came in E.D. after ingestion of 270 mg of AMT purchased on the internet [81]. The subject reported that he had used the same AMT lot of different times for its psychedelic properties, and to have miscalculated the last dose, ingesting a dose about 10 times higher than the previous. After an hour of ingestion presented hypertension (BP 183/93 mmHg, heart rate of 52 bpm), with normal respiratory rate and apyrexia. The patient was awake, hyper-alert, oriented with mydriasis (10 mm diameter), moderate tremor, delay in response times, restless, in exaggerated startle reaction and visual hallucinations. After 10 hours the symptoms begun to resolve. The diagnostic tests were normal, except for a slight value hypokalemia. He was discharged without complications.

Long reported during the EAPCCT XXIII International Congress the case of a patient (male, 17 years) arrived at the hospital with sympathomimetic effects after ingestion of AMT. The subject was found almost completely naked, while ran, and cried, and did not have previous medical or psychiatric history. He presented tachycardia (160 beats/min), extreme sweating (with temperature 37.28°C), and mydriatic pupils of 6-7 mm and reactive. The rest of the physical examination appeared normal, and the patient was immediately sedated with 6 mg lorazepam administrating by intramuscular route. Routine laboratory tests were normal, as well as the analysis of the cerebrospinal fluid and brain scan. Analysis of urine were negative for cannabinoids, cocaine, amphetamines, and phencyclidine. The day after the subject indicated the assumption of AMT, purchased on the Internet with the instruction for insufflation of 100 mg. The patient, however, reported that he had ingested the powder rather than take it by inhalation, with onset of symptoms after 15 min. HPLC analysis of the urine has confirmed the presence of the AMT and the absence of cocaine, phencyclidine, and amphetamines. The authors conclude that the intake of AMT involves rapid heartbeat, sweating, agitation and hallucinations and suggest supportive therapy, including sedation with benzodiazepines [82].

A case of intoxication after ingesting an unknown amount of DPT is reported in a 19 years old female by Dailey: when she arrived in E.D. presented hallucinations, extreme agitation and tachycardia (200 bpm). Clinicians administered 3 mg of lorazepam to resolve the state of agitation. Toxicological analysis did not reveal positivity for DPT: the assumption of DPT was ascertained only for the presence with the patient, of a vial with a label bearing the inscription "for research purposes only" [83].

Brush, reported a case of an adolescent (17 years old male) whose use of the Internet to obtain drug information

Table 6. Dosage and effects of most common synthetic 4-substituted tryptamines as reported on www.erowid.org [75].

4-substituted Tryptamines	Dosage (mg)	Duration of Action (Oral Administration)	“Positive” Effects
4-HO-MET (4-hydroxy-N-methyl-N-ethyltryptamine)	10-20	4-6 hours	With 20 mg: "Qualitatively a lot like psilocin. I started within the first half-hour, and at the max, I felt the same alteration of color and form, and times, sound was felt. As with psilocin, the experience was wave-like, with an alteration of effects between near-normal perception at one minute, only to be swept up in a swirl of altered concept the next minute."
4-HO-DET (4-hydroxy-N,N-diethyltryptamine)	10-25	4-6 hours	with 15 mg indolol: "Time really slowed down, with sparkly-ness, interesting, and yet there was a touch of sadness. The intense visuals held the scene, and there was the compulsion to talk and to interact and to share stuff, but the erotic was not to be found. I slept OK but there was something uncomfortable at a deep level. Am OK." with 15 mg phosphate ester: "The feelings I experienced could best be described as cosmic tenderness, infinite love, penetrating peace, eternal blessing and unconditional acceptance on one hand and, on the other, as unspeakable awe, overflowing joy, primeval humility, inexpressible gratitude and boundless devotion. Yet, all of these words are hopelessly inadequate and can do little more than meekly point toward the genuine, inexpressible feelings actually experienced." With 20 mg acetate ester: "A strange mixture of things at an hour, sedation, jaw-tightening, and a generalized body tremor. The light from the fireplace gave me bursts of color. Music allowed me to drift with my thoughts. Anorexia was intense. Four hours into it I was fine on the telephone to a friend who knew nothing about the day."
4-HO-DiPT (4-hydroxy-N,N-diisopropyltryptamine)	15-20	2-3 hours	With 15 mg: "There was an alerting, noisy and nice, in 30 minutes. Nice friendly place. Perhaps some light tension, like a chill, maybe my body temperature response is confused. At the two hour point I am substantially out of the experience. Short, intense experience, basically enjoyable." With 20 mg: "Early signs noted at 15-20 minutes which include mild sensation of central stimulation, 'loosening' of muscles in arms, legs, and neck. Mild distortion of objects and slight color effects, typically 'rainbow halos' around objects. Plateau reached in 20 minutes. 2.0 hours, mild effects. 2.5 hours, nearly normal. Mild but entirely pleasant experience with rather abrupt termination of effects."
4-HO-MiPT (4-hydroxy-N-isopropyl-N-methyltryptamine)	12-25	4-6 hours	With 12 mg: "The first awareness was unmistakable at twenty minutes, and from there it was a rapid and noisy development ending at about an hour. But this lasted for only another 40 minutes, and then dropped off quite rapidly. The erotic was excellent, but there were few visuals and I had difficulty connecting fantasy to music. Good appetite afterwards, and I had no trouble getting to sleep." With 30 mg acetate ester: "It was as if I had downed a few martinis in a hurry - except that there were eye-closed visuals in a lot of different colors, especially metallic greens. I had jaw clenching and a body tremor, reminding me of ecstasy except it was not in any way stimulated. I listened to music in front of a fireplace in a darkened room and I saw bright colorful unstructured patterns. Seven hours and I fell into an easy sleep and was fine the next day."
4-MeO-MiPT (N-isopropyl-4-methoxy-N-methyltryptamine)	20-30	4-6 hours	With 17 mg: "I am aware of this at 40 minutes, and was in a very light but not very well defined place for about two hours. It was neither good nor bad. It kind of drifted away and I was not sure when I regained baseline." With 26 mg: "This is my first try with this drug, ever. First indications of effects in twenty minutes. Quiet onset, no remarkable visuals, in fact no particular visuals at all. To a plus two within about ten or fifteen minutes more. Body is comfortable, mind-set pretty much unchanged from baseline. No euphoria, no insights. But also, no discomfort. Erotic was extremely successful. Still no visuals but seemed to be a soft plus three. Music fine. Hard to define exactly how we knew we were in an altered state, because of the lack of visual clues. Body aware more than mind. Would like to explore this further."

Table 7. Experiences of the users of some 5-substituted simple tryptamines reported by Alexander and Ann Shulgin [75].

5-substituted Tryptamines	Dosage (mg)	Duration of Action	“Positive” Effects
5-MeO-DET (N,N-diethyl-5-methoxytryptamine)	1-3 (oral administration)	3-4 hours	With 3 mg: "It hit in a half hour, and the thought that came to mind was the phrase from my days at college, "Boy, I really felt that drink!" I may be sloppy, but let me explore the sexual. Wow. I may be spacey in the head, but my body knows where it is at. The next day was normal. I don't think I want to do this again."
5-MeO-DMT (N,N-dimethyl-5-methoxytryptamine)	6-20 smoked 2-3 i.v.	1-2 hours	With 6 mg, smoked: "I felt it in a minute - not really light head, but the head feels close to the lower parts of the body - close to the ground - knees weak - distinct shakes. I peaked at 2 or three minutes. Slight nausea on the drop-off - I am glad I had not eaten anything. It's greatest contribution might be to provide a subject the vocabulary of an altered state of consciousness so that, with interesting and constructive drugs, these effects will be familiar, and thus not distractions." With perhaps 20 mg, smoked: "This is a very strong hallucinogen. A twenty minute experience. The 5-MeO-DMT was relaxed, a kind of cosmic consciousness type of experience. I broke into a space similar to DMT but it was more like receiving grace. I felt a little shaky (tremor-like) coming down." With 35 mg, orally: "No activity." With 2.3 mg, i.v.: " I thought I was an ocean. I don't remember where I first lost continuity of consciousness but I remember being aware of the sounds I was making apparently some time after I began vocalizing. Around the time I thought to change these sounds as I pleased, I also noted with brief wonder that the sound was continuous, not changed by my breathing. I sang my way back."
5-OH-DMT (5-hydroxy-N,N-dimethyltryptamine)	8-16 (i.v. administration)	1-2 hours	With 8 mg, i.v., over a 3 minute period: "I became lightheaded as soon as the injection started, and then my face turned purple and I became nauseated and I felt I couldn't breathe. I see white, straight lines with a black background. I can't trace a pattern. Now there are red, green and yellow dots, very bright like they were made out of fluorescent cloth, moving like blood cells through capillaries, weaving in and out of the white lines." With 16 mg, i.v., over a 3 minute period: "Almost immediately I felt a burning sensation in the roof of my mouth and I felt a tingling all over my body. My face turned purple, and my chest feels crushed. Everything has a yellow haze, and I was sweating heavily and I vomited. Words can't come. My mind feels crowded. When I start on a thought, another one comes along and clashes with it. I can't express myself clearly. I am here and not here. It has now been forty minutes and I feel better, but I still feel like I would like to walk it off, like a hang-over."
5-MeO-DiPT (N,N-diisopropyl-5-methoxytryptamine)	6-12 (oral administration)	4-8 hours	With 6 mg: "Effects were present in twenty minutes, and I took my portable radio into the garden at forty minutes just to pull weeds. Each weed had special significance, and my cat Ms. joined me and agreed with me. This is excessively strange. The radio was discussing a President Ford fund-raiser, and continued with word sequences such as fund, fun, profun, profound, profane, refrain, and on and on. A car drove by with sitar music playing on its radio! Why not. And by my hour number three, I am back where I started. That was quite a morning." With 12 mg: "Awful, awful taste. Quickly aware and in the second half hour I rapidly shot up in a very LSD-like manner, without the visuals. Time was quite slowed down during this come-on. Erotic world was fantastic, explosive, almost scary. Rapid drop-off, and by the fourth hour I am clear of any effects."
5-MeO-MiPT (N-isopropyl-5-methoxy-N-methyltryptamine)	4-6 (oral administration)	4-6 hours	With 4 mg: "Up very fast. Absolutely no visuals, but over the next two hours an ease of interpretive fantasy, almost dream-like, and easy eroticism. Food tasted marvelous, but there was no appetite. Easy, normal sleep." With 6 mg: "Rapid development to 45 minutes, some shakes, uneven handwriting, and hints of time slowing. Extremely erotic. Full plateau at the 2 1/2 hours. point, then a graceful and rather rapid drop. Easy, restful sleep. Absolutely no visuals or related sensory effects. Very pleasant, music extremely acceptable. "
5-MeO-DALT [77] (N,N-diallyl-5-methoxytryptamine)	12-20	2-4 hours	With 10 mg: "I am looking at everything through someone's open friendly eyes, not mine. I would like to go through life like this if others saw me as OK. I am 10 feet tall, my pulse is 72 but uneven, and light-headed is a better describer of where I am than psychedelized."

Table 8. Adverse effects related to tryptamine derivatives assumed.

Tryptamine	Adverse Effects
AMT	Nausea, vomiting (particularly common), anxiety, restlessness, muscle tension and palpitations.
DiPT	Ataxia, confusion and inner ear discomfort.
5-MeO-DiPT	Nausea, abdominal discomfort and diarrhoea.
4-substituted tryptamines	Lethargy, fatigue, anxiety, fear, paranoia, frightening hallucinations, intense overwhelming thoughts or visual disturbances, diaphoresis, flushing, elevated heart rate, muscle pain, confusion and difficult speaking.
5-substituted tryptamines	Terror, anxiety, fear, paranoia, frightening hallucinations, intense overwhelming experiences, respiratory discomfort or distress when inhaled, difficulty integrating experiences into normal life, nausea and vomiting at higher doses, headache, fatigue, muscle pain, abdominal discomfort, diarrhoea, minor bruxism.
5-MeO-DALT	Retrograde amnesia with higher doses.
Lysergic Acid Amide (LSA)	Anxiety, nausea, vomiting, abdominal pain, delirium, dizziness, confusion, fear and paranoia [79].

led to severe poisoning from the combination of a monoamine oxidase inhibitor, harmaline, and a hallucinogenic tryptamine, 5-methoxydimethyltryptamine (5-MeO-DMT) [84]. He purchased on the Internet some Syrian rue seeds containing harmaline, a natural MAOI [76]. After ingestion of seeds, smoking 10 mg of 5-MeO-DMT, and insufflation of further 15-20 mg, his friends found him collapsed, agitated and hallucinating. He arrived in E.D. with tachycardia (heart rate 186 bpm) and hyperpyrexia (40.7°C). He required physical restraint and clinicians administered to him 2.5 mg of IV lorazepam. This case illustrates the extreme danger of simultaneous administration of tryptamine with MAOIs: indeed, the concomitant use of harmaline and 5-MeO-DMT reduces deamination metabolism of the parent drug, leading to a prolonged and increased exposure to 5-MeO-DMT, as well as to its active metabolite bufotenine [57].

Wilson, reported the case of a 23-year-old man arrived to the Emergency Department after ingestion of a 5-MeO-DiPT homemade capsule. He did not lament visual nor auditory hallucinations, but only sensory distortion such as formication. Paranoia symptoms were observed. The patient was put under observation and then discharged. Toxicological analysis performed in blood and urine with gas chromatography–mass spectrometry revealed the presence of “Foxy” (5-MeO-DiPT) in the following concentration 0.14 (serum) and 1.6 µg/mL (urine), and its metabolite 5-methoxy-indole acetic acid was found in urine 0.17 µg/mL [85].

The ingestion of “Foxy” was associated with rhabdomyolysis and transient acute renal failure: Alatrash reported the ingestion of 25 mg of 5-MeO-DiPT in a healthy 23 years old man who arrived in E.D. presenting an altered state of consciousness characterized by hallucinations, tachycardia, hypertension and hyperpyrexia. Clinical investigations revealed renal impairment, metabolic acidosis and rhabdomyolysis. Toxicological analysis performed on a urine sample was negative for amphetamines, cannabinoids, cocaine, ethanol and barbiturates: the tests, executed in E.D., didn't confirm the presence of 5-MeO-DiPT [86].

The ingestion of an unusual dose of “Foxy” in a 19 years old man is reported by Smolinske. On arrival, he had

hallucinations, hypertension, tachycardia, mydriasis, and catalepsy. Laboratory analysis revealed hyperglycemia, glycosuria and an increased white cell count. A urine drug screening resulted positive for cocaine and phencyclidine: this test didn't reveal the presence of 5-MeO-DiPT. Symptoms were resolved within two hours after administration of lorazepam [87].

Meatherall described a 21-year-old man who arrived to the Emergency Department about 1.5 h after consuming a capsule to get high, named “Foxy”, and sold to him on the street: he presented no nausea, pain, or visual deficit, he was alert and oriented, the only relevant clinical observation was his inability to move his limbs. He denied taking any other recreational drug or alcohol. He had a blood pressure of 122/56 mm Hg, with 106 pulses and a respiration rate of 20. His pupils were equal and reactive with intact extra ocular movements and there was no motor sensory deficit. His cardiorespiratory examination was unremarkable. The patient received medical support until the symptoms did not disappear, about 3.5 hours after ingestion, then he was discharged from hospital. The toxicological analysis performed on the urine sample did not show presence of alcohol, but the immunoassay screening test was positive to cannabinoids and opiates: these results were, then, confirmed by GC/MS analysis. Acetaminophen and caffeine were detected in the acid-neutral drug screen performed with GC/MS. The GC/MS basic drug screen, indeed, revealed a large 5-MeO-DiPT peak, codeine, nicotine, cotinine, acetaminophen, caffeine, and two other peaks that were assumed to be 5-MeO-DiPT metabolites. The quantification of 5-MeO-DiPT was performed by GC/MS resulting at a concentration of 1.7 µg/mL in the urine sample [88].

The review of the American Association of Poison Control Centers' Total Exposure Surveillance System (AAPCC TESS) database found 41 exposures to “Foxy” between April, 2002 and June, 2003, resulting in moderate to severe toxicity in 68% of these cases. Clinical effects commonly involved agitation (59%), hallucinations (39%), tachycardia (37%), hypertension (17%), and confusion (15%). Tremors and seizures were rare [89].

Shimizu described a case of intoxication in a 27-year-old Japanese businessman after a single ingestion of the mixture of methylone and 5-MeO-MiPT: he had no previous psychiatric or medical illness and he had never used recreational drugs as methamphetamine, MDMA or organic solvents. The patient referred only sleep irregularities: he reported that, to solve his sleep disturbance, decided to take a drug without professional consultation. Although he did not know in depth the chemical and physical characteristics of methylone, he believed it could help feel him free from insomnia. Then, he bought on the Internet, the drug 1 g as pure methylone powder: but, toxicological analysis performed on the substance indicated that drug was composed of about 60% methylone (120 mg) and 38% 5-MeO-MiPT (76 mg). He took approximately 200 mg of the drug powder by oral administration and thirty minutes later, he started to feel nausea and sick in the stomach. When he arrived in hospital, he presented psychomotor excitement and he was shouting without apparent reason. He showed dilated pupils and sweating, pyrexia (37.8 °C), tachycardia (150 bpm) and his blood pressure was 144/81 mm Hg. After a gastric lavage a rapid drug screening device was used to examine a gastric fluid sample and urine: the assay systems showed no immunoreactivity for the most common drugs of abuse (phencyclidine, benzodiazepines, cocaine metabolites, amphetamine and methamphetamine, cannabinoids, opiates, barbiturates, and tricyclic antidepressants). He still exhibited symptoms of substance-induced psychomotor excitement, more than 3.5 h from drug administration. He was observed and received medical assistance until the following day, then discharged without any known sequel: however, he did not remember anything of what happened during acute intoxication [90].

Jovel described a case involving a 20-year-old college student brought to the E.D. after the ingestion of a dietary supplement capsule named "Lucy-N-Nate" that contained the novel synthetic tryptamine 5-MeO-DALT in unknown concentration. Although denying any other illicit assumption, his urine toxicological screening resulted positive for cannabinoids and amphetamines. At the admission he displayed diaphoresis, agitation, combativeness, flushes and warm sensation. Heart beat rate showed marked tachycardia (180–200 bpm) and tachypnea was observed. Benzodiazepines and haloperidol were administered in order to try to manage the patient's severe agitation with few results, therefore clinicians decided to proceed to deeper sedation and intubation. Rhabdomyolysis and acute renal failure were observed but resolved with supportive measures and the patient after three days was transferred to the inpatient psychiatric unit, and the following day he was discharged without symptoms or psychiatric sequelae [91].

FATALITIES INVOLVING TRYPTAMINE MISUSE

The use of tryptamines with recreational purposes may be associated with a higher risk of overdose, or due to a wrong dosage, as the information on these compounds available on the Internet are exclusively based on the first-hand personal accounts presented in discussion fora, or to a repeated administrations, because often the onset of the desired effects can occur at a distance of several hours from the assumption.

In February 2003, the Miami-Dade County Medical Examiner Department reported the first known death in the country related to the assumption of α -methyltryptamine (AMT). The case in Miami, involved a 22 years old college student who found deceased, about 12 hours after he confided to his roommate he was "taking hallucinating drugs" and he was able to "discover the secret of the universe". The roommate reported that he was shaking and sweating profusely, waving a knife, and threatening to commit suicide. The roommate tied him to the bed for his own protection and left him to "sleep it off". Approximately 12 h later, the roommate discovered the man lying in bed unresponsive. From the scene was recovered an empty 1-g vial of AMT. Immunoassay analysis of urine and gastric contents performed with enzyme immunoassay technique were positive for amphetamines and the basic drug blood screen performed with GC/MS detected a small peak, later identified as AMT. Volatile substances were screened using headspace gas chromatography (GC/HS). Postmortem toxicological analysis performed on iliac vein blood, gastric contents, liver and brain revealed the presence of AMT in the following concentrations (Table 9) [92, 48].

Table 9. Concentrations of AMT in the specimens collecting during autopsy from Moffat.

Specimen	AMT Concentration
Iliac vein blood	2.0 mg/L
Gastric contents (48 g collected during autopsy)	9.6 mg total
Liver	24.7 mg/kg
Brain	7.8 mg/kg

Several deaths have been attributed to AET (α -ethyltryptamine) assumption: this compound, strictly related to α -methyltryptamine, has psychedelic, stimulant, and entactogenic effects. It was originally developed as an antidepressant (Monase[®]) by Upjohn chemicals company in the 1960s but it was withdrawn from potential commercial use, because of an unacceptable incidence of idiosyncratic agranulocytosis [19, 93].

Morano reported a case of a 19 years old female who ingested a glass of beer containing two 'hits' of white powder that she described as MDMA. After ingestion she became confused, vomited and had a cardiac arrest. Autopsy revealed bilateral "pulmonary edema and generalized visceral congestion with some epicardial petechiae". Toxicological findings showed the following AET tissue distribution: blood (heart) 5.6 mg/L, urine 80.4 mg/L, vitreous 2.4 mg/L, bile 22.0 mg/L, stomach contents 52.9 mg.; in liver, kidney and brain AET was found in a concentration of 18.3 mg/g, 24.0 mg/g and 16.2 mg/g respectively. MDMA was not revealed in autoptical samples [94].

Another case of fatal intoxication with AET is reported by Daldrup. After ingestion of α -ethyltryptamine a young

man developed agitation, hyperpyrexia: he showed effects similar to those known from intoxication with amphetamines, MAO inhibitors, and thymoleptics. The exact amount of α -ethyltryptamine taken are not known, but it could have been in the range of 700 mg. The level in postmortem blood was 1.1 mg/l. Malignant hyperthermia is discussed as a possible cause of death [95].

In 2005, a 25 years old white male was found dead in a national park, where he was camping with his family, the morning after consuming a herbal hallucinogenic extract containing β -carbolines and hallucinogenic tryptamines [96]. An autopsy was performed the day after the body was discovered and no anatomic cause of death was found. "External examination identified only the presence of lividity that was fixed on the posterior surface of the body, except in areas exposed to pressure. Internal examinations, both gross and microscopic, were unremarkable except for some tissue congestion and edema". Toxicological analysis were performed on specimens (central and peripheral blood, urine, gastric contents, bile, kidney, brain, and liver) collected at autopsy. The heart blood and urine samples were tested for volatile substances (methanol, ethanol, acetone and isopropanol by headspace gas chromatography) and therapeutic and abused drugs: no ethanol or other volatile substances were detected. Diphenhydramine was detected exclusively in the urine sample. "An unidentified peak was detected in both the blood and urine specimen on the alkaline drug screen: subsequent mass spectral analysis identified the substance as 5-MeO-DMT". In the heart blood sample was identified N,N-dimethyltryptamine (0.02 mg/L), 5-methoxy N,N-dimethyltryptamine (1.88 mg/L), tetrahydroharmine (0.38 mg/L), harmaline (0.07 mg/L), and harmine (0.17 mg/L). Tetrahydroharmine (THH) "was present in higher amounts than both harmaline and harmine in all samples with the exception of the gastric contents, where the amount of harmine was 10-fold greater than that of THH". The medical examiner ruled that the cause of death in this case was hallucinogenic amine intoxication.

Tanaka reported a fatal case of intoxication with "Foxy" (5-methoxy-N,N-diisopropyltryptamine). The decedent (male A) was a 29-year-old. The male A was a sexual partner of male B, who injected an aqueous solution of 5-MeO-DiPT into the anus of male A using a dropper, with the aim of enhancing sexual pleasure. Following the rectal administration, male A showed adverse effects including abdominal symptoms and intense agitation, so he was rushed in hospital, but he died on the following day. "Autopsy findings revealed periarteritis nodosa, involving the heart and liver, an area of myocardial ischaemia, leukocytosis, advanced pulmonary congestion and pulmonary alveolar haemorrhage and periprostic bleeding. Blood and urine specimens were submitted for toxicological examination": 5-MeO-DiPT and its two metabolites, 5-hydroxy-N,N-diisopropyltryptamine (5-OH-DIPT) and 5-methoxy-N-isopropyltryptamine (5-MeO-NIPT), were identified by LC-MS. The level of 5-MeO-DIPT, 5-OH-DIPT and 5-MeO-NIPT in blood was 0.412, 0.327 and 0.020 $\mu\text{g/ml}$, while their concentrations in urine sample were 1.67, 27.0 and 0.32 $\mu\text{g/ml}$, respectively. These blood and urine levels were higher than published data for such poisoning. "In addition, no ethanol, therapeutic and

abused drugs were detected in serum and urine specimens in this case. Based on the autopsy and toxicological findings, the cause of death was acute cardiac failure due to neurotoxicity resulting from an overdose of 5-MeO-DiPT" [62]. Unconfirmed reports on the Erowid website hypothesized that a 100 mg dose was used rectally, while a normal dose would be 10 mg [97].

In some cases the death of users of tryptamines for recreational purposes, was not caused by overdose or incorrect dosages, but by changes in the state of consciousness that led to the outbreak of irrational behaviors, extremely dangerous.

A 26 years old male was killed after walking onto the slow lane of a motorway and being hit by a lorry. He was seen to walk in front of a heavy goods vehicle while he was grinning. "At the inquest it was reported that he had snorted 350 mg of 5-MeO-DALT" [98] "(when the normal dose is 25 mg) in a public house with a friend who bought 1 g of it over the Internet". During the autopsy, the coroner found a significant head injury with a base of skull fracture, cerebral and pulmonary contusions. The pathologist recorded the cause of death as "fractured base of skull" [10].

An initial toxicological investigation found that the postmortem femoral blood contained an atracurium breakdown product (laudanosine) and propofol, which presence is consistent with medical intervention. The blood alcohol concentration was 22 mg/dL. "A compound was detected in blood with a distinctive tryptamine-like UV spectrum, but tryptamine itself is also regularly observed as a putrefactive compound. No other drugs were detected". Following "further information about the deceased's consumption of 5-MeO-DALT, supplementary toxicological analysis of the post mortem femoral blood samples were undertaken, using liquid chromatography with mass spectrometry detection (LC-MS), as it can be difficult to distinguish between tryptamine and other naturally occurring tryptamine-related compounds and those with methoxytryptamine derivatives (including 5-MeO-DALT) with similar UV spectra". LC-MS analysis indicated that the compound was 5-MeO-DALT, but there are no information about its quantification.

It was reported another case of death [99] of a man who, after ingesting Hawaiian baby woodrose seeds [100], jumped from a building: ergine was found in his post mortem blood and urine [11].

ANALYTICAL METHODS FOR TRYPTAMINES

Tryptamines are not routinely detected with common immunoassay-based techniques, leading, for example, to misunderstanding in diagnosis or therapy in Emergency Departments, as toxicological screening tests could result completely negative.

Extensive laboratory analysis is required for the identification of these compounds, involving the use of techniques with high selectivity and sensitivity such as mass spectrometry (MS). But, even using powerful instrumentations, the new substances could be missed, either because, working in a full-scan mode, reference mass spectra are not yet included in libraries, or because the fragments generated

during the analysis in selected ion monitoring (SIM) show nondescript and not monitored fragmentation patterns [76].

Moreover, instrumental screening methods were developed also for other NPS, but they do not always include tryptamines [101-103].

Several analytical approaches for tryptamines were published in scientific literature since 2003. Both screening methods [104-107] and confirmatory methods were developed for the detection of tryptamine derivatives which had clinical and forensic relevance [62, 85, 88, 90, 92, 96,

105, 106, 108-111], using the hyphenated chromatography (GC and LC) mass spectrometry approach.

Whole blood, serum, plasma and urine were used for clinical studies [85, 88, 90, 104, 110, 111], while several biological matrices were investigated for forensic purposes [62, 92, 96].

Different extraction methods and sample preparation procedures were proposed: liquid liquid extraction (LLE) [62, 85, 88, 96, 112], solid-phase extraction (SPE) [92, 104,

105, 108, 109, 111], dilution in solvent [107, 110, 111, 113, 114] and protein precipitation (PP) [106].

The separation techniques used were gas chromatography (GC) and High Performance Liquid Chromatography (HPLC): in some recent papers, Ultra High Performance Liquid Chromatography (UHPLC) was used providing a more efficient analysis in a shorter time [106, 111]. The separation techniques were coupled with mass spectrometers, mainly for forensic purposes.

Several analyzers were used: (1) a single quadrupole in full-scan mode [90, 107, 112-114] and in SIM mode [62, 92, 96, 104, 108, 109]; (2) a quadrupole ion trap in full-scan mode [88]; (3) a triple quadrupole in the following analyzer mode: MRM, SRM, PIS, IDA and in full-scan mode [105, 110-112]; (4) a high resolution Orbitrap [114]. It was also used a TOF analyzer with MALDI ionization system, in order to compare the fragmentation pattern with that obtained with other analyzers [107].

Results of analysis of substances seized from law enforcement agencies were published too [90, 107, 113, 114], resulting in a useful source of information for specialists, including the personnel working in Emergency Departments. When NPS are found, if a reference standard is not available, NMR is needed for structural elucidation. Infrared (IR) spectroscopy is another powerful tool for bulk analysis. Hugel reported both the IR spectra and MS spectra of N,N-dimethyltryptamine, N,N-diethyltryptamine, N,N-dipropyltryptamine, and 5-methoxy-N,N-diisopropyltryptamine [115].

Key information of selected analytical methods reported in scientific literature is summarized in Table 10.

CONCLUSIONS

Many psychoactive substances belong to the chemical class of tryptamines. There are old compounds known for their hallucinogenic properties, such as psilocybin in 'Magic mushrooms' and dimethyltryptamine (DMT) in Ayahuasca brews, and there are several *New psychoactive substances* (NPS), emerging drugs whose chemical structures are similar to other psychoactive compounds but not identical, so that they represent a "legal" alternative to internationally controlled drugs. The comprehensive review of the published literature carried out permitted to find not only many scientific publications but also useful information from non peer-reviewed sources, including media reports and Internet resources such as drug user web fora. It was possible to collect and organize information on chemical characterization, pharmacology and toxicity of these drugs, according to a proposed classification based on their chemical structures. The articles, reporting cases of death related to intake of these substances, showed the need of more effective policies to promote timely exchange of information. Internet is "a growing source of on-line drug trafficking": products purchased on Internet may vary over time proposing chemicals always different, not listed in literature, meaning that users are often unaware of what or how much they are taking, causing increasing risks to public health. For this reason information from Internet, together with results of analysis of substances seized from law

enforcement agencies and reports of cases of death related to intake of these substances, organized in the way we proposed in this review, provides an effective tool for specialists facing this emerging threat to public health and public security, not only forensic scientists but also the personnel working in Emergency Departments.

CONFLICT OF INTEREST

The authors confirm that this article content has no conflict of interest.

ACKNOWLEDGEMENTS

Declared none.
