The Journal of Rheumatology is a monthly international serial edited by Earl D. Silverman featuring research articles on clinical subjects from scientists working in rheumatology and related fields.

Possible Implication of Red Blood Cells in the Prothrombotic Risk in Early Rheumatoid Arthritis

To the Editor:

Rheumatoid arthritis (RA) is an autoimmune inflammatory disease that can be considered as a prothrombotic state¹. A great number of studies have investigated the possible role of reactive oxygen species (ROS) in the etiology and pathogenesis of this disease. The presence of large amounts of superoxide radicals and hydrogen peroxide produced by activated neutrophils has been reported in the synovial fluid of patients with RA. This may cause lipid peroxidation that yields a wide variety of end products, including malondialdehyde (MDA), a known marker of oxidative stress. These products are therefore transported from the synovial fluid to the blood circulation system². Considering that elevated levels of MDA have been observed in the blood plasma of patients with RA², the aim of this pilot study was to investigate whether the elevated levels of plasmatic MDA could be associated with a modification of the total antioxidant capacity (TAC) of blood plasma that is usually indicative of a "systemic" oxidative imbalance³. In addition, in view of their activity as redox effectors or scavengers⁴, as well as determinants of thrombus formation⁵, we evaluated red blood cell (RBC) features in terms of their redox state and lifespan marker molecules.

In our pilot study, 15 women with early RA (median age 44 yrs, range 20–56; median disease duration 24 weeks, range 12–60) and 15 age- and sex-matched healthy donors (HD) were included. Patients with RA were diagnosed according to the 2010 criteria of the American College of Rheumatology and European League Against Rheumatism⁶. Patients were excluded from the study if they had congenital heart disease, previous myocardial infarction, thrombotic events, renal or hepatic dysfunction, cancer, human immunodeficiency virus infection, or hepatitis. All patients (1) had active disease, defined as 28-joint Disease Activity Score 4.26 ± 1.27 ; (2) had not yet been treated for RA; and (3) had no comorbidities, such

as hypertension, hyperglycemia, hypercholesterolemia, or cardiovascular risk factors. Interestingly, no patients had anemia, and all showed high levels of C-reactive protein (CRP) and high values of erythrocyte sedimentation rate (ESR; Figure 1).

The nature and the purpose of our study were explained to all participants who gave their informed consent following the rules of good medical practice. This study was approved by the Institutional Review Board of "Sapienza" University of Rome, Italy, according to the principles outlined in the Declaration of Helsinki.

Plasma and RBC were isolated by centrifugation of whole blood⁷. RBC redox balance (levels of ROS and total thiol content), and expression of molecules involved in RBC senescence (CD47) and injury [Phosphatidylserine (PS) externalization] were evaluated as previously reported⁷. Expression of molecules responsible for RBC survival [survivin and extracellular signal-regulated kinase (ERK)] was evaluated by static (not shown) and flow cytometry using monoclonal antibodies (Santa Cruz Biotechnology and BD Biosciences). MDA and TAC were evaluated using commercially available ELISA immunoassay kits. The Mann-Whitney U test was used to compare quantitative variables in different groups. Flow cytometry data were statistically evaluated using the Kolmogorov–Smirnov nonparametric test⁷ according to the Cell Quest Pro software guide (BD BioSciences).

In our study, we found that (1) as expected, plasmatic MDA levels were significantly higher ($p < 0.05$) in patients with RA (median $2.62 \mu\text{g/ml}$, range 1.2–4.3) than in HD (median $1.73 \mu\text{g/ml}$, range 0.8–2.6), and (2) TAC of blood plasma was significantly reduced ($p < 0.005$) in patients with RA (median 2.8 mM, range 2.2–5.4) compared to HD (median 21.35 mM, range 3.1–30.4). Interestingly, this does not seem to significantly interfere with the redox state of RBC and with externalization of PS. In fact, a mild production of ROS and a mild reduction of total thiol content have been detected in RBC from patients with RA. Similarly, no differences have been found in the percentage of RBC showing PS externalization (evaluated in

RA: rheumatoid arthritis; HD: healthy donors.

terms of percentage of annexin V-positive RBC; Figure 2A, 2B, and 2C) and in the expression of CD47 (Figure 2D). Conversely, survivin ($p < 0.001$; Figure 2E) and phosphorylated ERK ($p < 0.001$; Figure 2F) were significantly higher in RBC from patients with RA than in those from HD. CD47 is an integrin-associated protein, known as the thrombospondin receptor, which acts as a marker of self. Survivin is a member of the inhibitor of apoptotic protein family. ERK is a mitogen-activated protein kinase whose phosphorylation induces (1) upregulation of survivin⁸, and (2) increase of RBC adhesion to the endothelium⁹. Hence, our data, although obtained in a small cohort of patients, seem to indicate that in patients with RA, a mild alteration of intracellular redox state of RBC can occur. This is associated with activation of ERK signaling pathway and overexpression of survivin. This possibly leads to alterations of RBC homeostasis that, together with increased ESR and inflammatory protein CRP¹⁰, could alter blood flow¹.
