## ABSTRACT

We have explored by means of *ab initio* molecular dynamics two Ionic Liquids based on the combination of the choline cation with deprotonated cysteine and aspartic acid anions. While the combination of the strong base choline with various other amino-acids leads to the formation of a highly ionized medium where proton transfer is negligible, the presence of additional protic functions on the SH and the COOH groups leads to an unexpected and interesting behavior and to a sizable migration of their acidic protons onto the NH<sub>2</sub> basic terminals. As far as we know this is the first time that such proton migration, which in water leads to the well-known zwitterionic form of aminoacids, is seen to take place in their ionized, anionic form. We analyze in details such dynamical effects using accurate *ab initio* molecular dynamics computations validated through comparison with X-ray diffusion data.

## 1. Introduction

From a general point of view an ionic liquid (IL) is a substance made entirely by ionic couples that, due to its being liquid at room temperature, presents several specific

<sup>+</sup>Present address: Laboratoire LECIME, CNRS UMR-7575, Chimie-ParisTech, 11 rue P. et M. Curie, F-75231 Paris, France

properties<sup>1</sup> which make it an interesting subject of research due to the increasing number of possible technological and industrial applications<sup>2-5</sup>. In addition, the low environmental impact of ILs (due to their negligible vapor pressure) makes them an optimal candidate as benign and less harmful solvents in industrial processes. Given the huge number of anion-cation combinations, the possibility of providing ILs with special features has given them the reputation of “designer materials” whose properties can be tailored for specific applications. Particular attractive is the possibility of creating special ILs that are fully biocompatible. The implementation of these materials has opened new routes in their application in the pharmacological and biomedical fields and, in general, in green-chemistry processes<sup>6-9</sup>. In this respect a new generation of ILs has been synthesized in which the typical inorganic anions such as  $[\text{PF}_6]^-$ ,  $[\text{BF}_4]^-$ ,  $\text{Br}^-$ ,  $\text{Cl}^-$ , have been substituted by organic amino acid anions<sup>10</sup>.

In this work we focus on two ILs consisting of a choline cation  $[\text{Ch}]^+$ , mixed with two amino-acid anions<sup>11</sup>: cysteine  $[\text{Cys}]^-$ , and aspartic acid  $[\text{Asp}]^-$ . This class of ILs, given that both constituents play a role in metabolic processes, was proven to be non toxic for the humans and for the environment<sup>12-14</sup>, and can be considered a promising class of materials for a large range of bio-related applications<sup>15-17</sup>.

Given that, formally, these liquids come from an acid base reaction, they fall into the broad class of ILs called Protic IL (PIL)<sup>18-21</sup>. Despite the simplicity of the composing molecular ions, these class of ILs can show a very complex structural and dynamical behavior due to the occurring of nano-segregation phenomena<sup>22-23</sup>. In these particular set of ILs there is a noticeable and peculiar network of hydrogen bonds<sup>24</sup> whose strength obviously depends on the ionic partners and their relative acidity.

In general, the degree of ionization in a PIL depends upon the  $\Delta\text{pK}_a$  between the acid and the conjugate acid of the base<sup>25</sup>. The larger the  $\Delta\text{pK}_a$ , the more ionized the final material will result. For very low  $\Delta\text{pK}_a$  no proton transfer occurs and the system remains composed of neutral species. At higher values of  $\Delta\text{pK}_a$  we have an intermediate situation where the proton is only partially transferred to the base<sup>26</sup>. Finally, when the  $\Delta\text{pK}_a$  is sufficiently large the ensuing liquid is completely ionized. A system made by a choline cation ( $\text{pK}_a \sim 13.9$ ) and an amino-acid ( $\text{pK}_a \sim 2-2.4$ ) represents a typical situation falling in the third case (large  $\Delta\text{pK}_a$ ) where the final liquid medium is completely made by ionic

partners. Such ideal case can be easily treated and modeled via classical (topologically fixed) MD simulations.

In a completely ionized liquid (namely an IL) the charge transport is due to the ionic motion and its conductivity is inversely proportional to the viscosity of the fluid that is generally high leading to the well known, poor conducting behavior of many ionic liquids. Unfortunately, allowing proton diffusion by using an acid-base pair with smaller  $\Delta pK_a$  usually further reduces the conductivity because the concentration of charge carriers (the ions) decreases. In addition a non completed ionization reaction often leads to other problems such as phase separation and to a high volatility of the polar, non ionic phase. It is therefore of great relevance for electrochemistry the discovery of fluids where the degree of ionization is still complete (so that they maintain the useful properties ascribed to ILs) but proton diffusion could occur<sup>27 28</sup> via other mechanisms.

The two PILs that are the subject of this study have an amino-acid anion that presents an additional protic function and proton transfer from these groups (-SH or -COOH terminals) to the -NH<sub>2</sub> terminal is possible. With this prescription the choline cations would remain simple spectators and therefore the cation choice may represent an additional, useful degree of freedom to further enhance or tailor specific properties. In order to allow the proton transfer we have however to face another additional problem: in ionic liquids the local, short-range geometry of the fluid is characterized by an alternating pattern of ions and counterions. Since both the acidic functions and the basic one are located on the anion, for proton transfer to occur, two anions must be close enough in the fluid. This means that the molecular anions should present some sort of attractive interaction between each other. As we shall see, these interactions can be mediated by H-bonds.

Given the rather complex chemical morphology of the compounds we are dealing with, these systems has to be treated realistically only via *ab initio* molecular dynamics (AIMD) where the topology of the chemical bonds is not held fixed.

## 2. Methods

### 2.1 Computational methods

We have performed different AIMD simulations of the bulk system composed by an equal number of amino acid anions and [Ch]<sup>+</sup>cations. A pre-equilibration was performed employing classical molecular dynamics within periodic boundary conditions, using the AMBER program package<sup>29</sup> and the Gaff force field<sup>30,31</sup> for 1 ns of physical time at 350 K. The starting configurations yielded by this procedure were used to setup *ab initio* molecular dynamics simulations:

The [Ch][Cys] system has been modeled as described in ref. <sup>32</sup> using the program CP2K<sup>33</sup>, the Quickstep module<sup>34</sup> and the orbital transformation<sup>35</sup> for faster convergence. The electronic structure was calculated by means of the PBE<sup>36</sup> functional, with an explicit Van der Waals correction that includes the empirical dispersion correction (D3) by Grimme<sup>37</sup>. Basis sets of the kind MOLOPT-DZVP-SR-GTH and GTH pseudopotentials<sup>38,39</sup> were used. The timestep was chosen to be 0.5 fs and the simulation temperature was set at 350 K using the Nose-Hoover thermostat<sup>40</sup> in order to slightly accelerate the dynamics which is very slow at ambient conditions due to the high viscosity of these systems<sup>11</sup>. The cell has a side-length is 25.6 Å and contains 56 ionic pairs; production time was 24 ps with a constant density of 1.24 gr/cm<sup>3</sup> (the experimental value is 1.18 gr/cm<sup>3</sup>).

The [Ch][Asp] simulation has been instead performed using the CPMD<sup>41</sup> code. The cell has a side length of 18.0 Å and contains 16 ionic pairs. Car-Parrinello molecular dynamics has been performed employing the PBE functional and Troullier-Martin<sup>42</sup> pseudopotentials (PP) for first row elements. Production time was 56 ps at 300 K with a constant density of 1.07 gr/cm<sup>3</sup> (the experimental value is approximately 1.1 gr/cm<sup>3</sup><sup>43</sup>).

*Ab initio* calculations for the isolated molecules have been performed with Gaussian09<sup>44</sup>. Optimization and frequencies have been calculated at the MP2/6-31G\* level. Wavefunction analysis (such as multipoles and charges) have been determined using the MP2/6-311G\*\* and MP2/6-311++G(2d,2p) levels respectively at the MP2/6-31G\* geometry.

The trajectory post-processing and the investigation of structural properties have been carried out with the TRAVIS package<sup>45</sup> and “in house” software codes.

## 2.2 Experimental X-ray structure factors and their computations

For the synthesis of the [Ch][AA] ILs, we used, with slight variations, the method recently reported in the literature by our group<sup>11</sup> and we shall not report here the details.

The large angle X-ray scattering experiments were performed at room temperature using the non commercial energy-scanning diffractometer built in the Department of Chemistry at the University 'La Sapienza' of Rome (Italian Patent No. 01126484-23 June, 1993). For a detailed description of instrument, technique, and the experimental protocol of the data acquisition phase, the reader is referred to refs.<sup>46 47 48 49</sup> and specifically to these systems to ref<sup>32</sup>.

The total intensity of the radiation scattered by the sample, after the correction for systematic effects and rescaled to absolute units (electron units per stoichiometric unit), can be expressed as the sum of the independent atomic scattering and of  $I(Q)$ , the 'static structure factor' that constitutes the structurally sensitive part of the scattered intensity due to the interference contributions.  $Q$  is the magnitude of the transferred momentum. The function  $I(Q)$  is related to the atom-atom pair correlation functions, according to the formula:

$$I(Q) = \sum_{i=1}^N \sum_{j=1}^N x_i x_j f_i f_j \times \left[ 4\pi\rho_0 \int_0^\infty r^2 (g_{ij}(r) - 1) \frac{\sin Qr}{Qr} dr \right]$$

where  $\rho_0$  is the bulk number density of the system,  $x_i$  are the numerical concentrations of the species and  $f_i$  the  $Q$ -dependent X-ray scattering factors. Both the experimental and theoretical structure functions have been multiplied by a modification function

$$M(Q) = \frac{f_N^2(0)}{f_N^2(Q)} \exp^{-0.01Q^2}$$

that is useful to improve the curve resolution at high  $Q$ . In the plots we shall always report the product  $I(Q)M(Q)Q$ .

### 3. Discussion and results

We had already provided in ref.<sup>50</sup> a preliminary study of choline-based ILs by focusing on their docking morphology for the isolated ionic couples in the gas phase. The results from a series of high quality *ab initio* simulations have clearly shown that the docking geometry of the compounds behaves in a very similar manner along the entire series. The main intermolecular bonding feature is a strong hydrogen bond between the OH group on  $[\text{Ch}]^+$  and the carboxylate of the aminoacid. This bonding feature represents substantially the driving force of aggregation beyond the obvious electrostatic cohesive force. We have further confirmed these important results in a second and third study<sup>51,32</sup> that focused on the behavior of the liquids obtained by a homologue series of molecular anions made by 11 different amino-acids. As we previously noticed in ref.<sup>32</sup>, a peculiar case among those studied, is represented by the  $[\text{Ch}][\text{Cys}]$  material where intra- and inter-molecular proton transfer occurs from the  $-\text{SH}$  to the  $-\text{NH}_2$  terminal.

An even more complicated liquid arises when mixing the  $[\text{Ch}]^+$  cation with the  $[\text{Asp}]^-$  amino-acid anion where we have a second carboxylic acid function. The systems under study and their chemical structures are shown in Scheme 1.

#### 3.1 The simulation of the $[\text{Ch}][\text{Cys}]$ ionic liquid

The  $[\text{Ch}][\text{Cys}]$  is an IL that comes from the deprotonation reaction of an amino-acid with two acidic hydrogen atoms. As shown in ref.<sup>11</sup>, the IL formation reaction can proceed with the abstraction of one proton (the one on the carboxylic acid) and form a completely ionized IL. The reaction can then be further continued removing also the second proton (the one on the  $-\text{SH}$  terminal) and in this case a solid is obtained that has a melting point above  $90^\circ$ .

The liquid conductivity of the  $[\text{Ch}][\text{Cys}]$  is very likely due to a poor “Walden” mechanism since it linearly correlates with the inverse of the viscosity, which is high<sup>11</sup>. It therefore follows that this liquid is not a candidate for fast proton transfer, nevertheless its microscopic structure turns out to be quite peculiar and points to a possible mechanism with which one could, in principle, obtain a neat, dry IL with conductivity mediated by proton transfer.

The existence of a relatively mobile proton on the –SH moiety makes this system extremely complicated from the nanoscopic point of view. As we have already pointed out in ref. <sup>51</sup>, during our simulations few [Cys] anions underwent an intramolecular proton transfer from the –SH terminal to the –NH<sub>2</sub> group (see Scheme 2). As we have already discussed in the aforementioned paper, the intramolecular proton transfer leads to the formation of a molecular ion with a triple charge separation. We had found by simple gas phase computations that this zwitterionic anion (**Cys-Z**) turns out to be 2-4 kcal higher in energy than its ionic counterpart<sup>51</sup> (**Cys-N**).

In order to further investigate this behavior, here we have repeated the computation of the relative energy of two isomers (**Cys-N** and **Cys-Z**) in the gas phase and in a solvent whose dielectric constant matches that of a typical protic ionic liquid ( $\epsilon=35.7$ ) using both the MP2/6-31G\* and the PBE/6-311+G\*\* methods. The resulting MP2 optimized gas-phase structures of the two anionic isomers **Cys-N** and **Cys-Z** are reported in Figure 1 along with the charge density colored with its electrostatic potential. The relative energy of the isomers along with that of the transition state between them is reported in Table 1 where we can see that in a solvent with a medium dielectric constant ( $\epsilon=35.7$ , similar to those typical of a protic ionic liquid<sup>52</sup>) the relative stability of the structures is reversed or at least attenuated with respect to the gas phase. Anyway, the inter-conversion barrier is low enough that we expect to see a consistent transformation of the [Cys] anion from the **cys-N** to the **cys-Z** form.

Structure	$\Delta E$ Gas-phase (kcal)		$\Delta E$ (Solvent $\epsilon=35.7$ ) (kcal)	
	MP2/6-31G*	PBE/6-311+G**	MP2/6-31G*	PBE/6-311+G**
<b>Cys-N</b>	0.0	0.0	0.0	0.0
<b>Cys-Z</b>	5.0	4.2	-0.6	0.8
TS <sup>#</sup>	6.4	2.7	4.5	1.5

*Table 1: Relative Energy (including zero-point-energy differences) between the optimized structures of the two isomers of [Cys] along with the energy of the inter-conversion barrier.*

We now move to the description of the results that we can obtain from the AIMD simulations. We report in Figure 2 the development of the S—H and N—H distances (within the same ion) in 6 selected molecules along the AIMD trajectory. As we can see, during the (limited) time span of our simulation we can easily identify at least four complete intramolecular proton transfers from the —SH to the —NH<sub>2</sub> group (panels 3, 4, 5 and 6 in reading order). In panel 1 we have reported an example where the proton is moving between the two basic groups via a strong H-bond between the resulting —NH<sub>3</sub><sup>+</sup> and the —S<sup>−</sup> terminals while in panel 2 we see instead a situation where the proton, initially on the —SH group, “jumps” back and forth on the amino group atom several times, giving rise to a complicated dynamics.

A typical ionic liquid generally exists in a mobile, but structured array of ions in which every cation is surrounded by anions and vice versa. The fact that the anions are generally separated by a cation limits the possibility of direct contacts between them. This is the reason why we see mostly intra-molecular proton transfers. For the same reason it is much more difficult to see an inter-anionic one. Despite the electrostatic repulsion, two anions may come in close contact if they have the possibility of forming a strong H-bond between the —SH and —NH<sub>2</sub> terminals.

In order to investigate this intriguing possibility we report in Figure 3 three radial distribution functions (RDFs) within the same anions and between different anions. In the left panel we report the RDFs for the N—H (black line) and S—H (red line) distances where we see the dominant S—H motifs (structure **cys-N**) with a typical S—H distance of 1.38 Å (see also Figure 2) and the less occurring —NH<sub>3</sub><sup>+</sup> motif (structure **cys-Z**) with an N—H distance of 1.06 Å. The **cys-Z** motif can also be identified by the second broader, weaker peak in the S—H RDF (red line) with a maximum slight above 2.0 Å which correspond to the distance of the S···H—N hydrogen bond occurrence seen in Figure 2. On the right panel, instead, we report the inter-molecular (anion-anion) N--HS distance. The H-bond pattern already seen within the same anion is repeated here with a first peak at 1.11 Å pertaining to a **cys-Z** motif (with a S···H—N pattern) and a broader one at 1.8-1.9 Å due to the **cys-N** state (with an S—H···N pattern). This last example tells us clearly that several anions establish strong H-bonds between them.

Although we have found several occurrences of strong H-bond between different anions, we show here a peculiar case where a complex proton transfer dynamics takes place between 3 different anions bound together by S—H—N H-bonds. The situation is graphically depicted in Figure 4 where we report several snapshots of the simulations, but we draw only the three anions involved in the proton exchange. At the beginning of the simulations both active protons (colored in magenta in Figure 4) are bound to the sulfur atom (panel 1) and the chemical environment is a (cys-N)<sub>3</sub> cluster. After 2 ps (panel 2) we see a first proton transfer from the anion on the left to the central one. After 3 ps (panel 3) the first proton has gone back to the sulfur atom while the one from the anion on the right has been transferred to the central one. Between 10 and 12 ps both protons are again on the two sulfur atoms (panel 4). At 12.5 ps the anion on the right undergoes an intramolecular proton transfer (panel 5) while the anion on the left definitely transfers its proton to the central one (panel 6). After 24 ps, the system becomes a (cys-N)(cys-Z)<sub>2</sub> cluster<sup>†</sup>.

### 3.2 [Ch][Cys]: final remarks and experimental validation

Since [Ch][Cys] does not seem to be a particularly good current conductor<sup>11</sup>, it is very likely that the isomerization reaction from cys-N to cys-Z reaches a dynamic equilibrium and that the proton does not move through the ionic medium. It is possible that the event of inter anionic proton transfer noticed above is only a sporadic event in the fluid not sufficient to sustain a proton “jump” mechanisms apt to carry charge. The isomerization reaction is however an interesting and unexpected feature of this IL and strongly influences the local microscopic structure and properties of the liquid. As shown in ref.<sup>11</sup>, the fact that some of the PILs based on choline and amino-acids (specifically [Cys], [Ser] and [Lys]) have much higher viscosities with respect to others members of the series has been attributed to their capacity of forming additional hydrogen bonds thanks to the heteroatom on the side chain. We believe that in these amino-acids the above isomerization reaction can take place (to various extent) and that this might play also a role in determining their dynamical behavior. In particular the additional charge

---

<sup>†</sup>The additional proton that is transferred to the central molecule cannot be shown for graphical reason.

separation of the anionic-zwitterionic form might slow down ions diffusion and dynamics.

In order to support our theoretical results, we report in Figure 5 a comparison between the calculated and measured  $I(Q)M(Q)Q$  for the [Ch][Cys] system. As we can see the agreement between the theoretical and experimental patterns is excellent with the possible exception of the intermediate range region (medium values of  $Q$  in the graph). This discrepancy can be easily explained by assuming that the proton migration reaction and therefore the isomerization from the **cys-N** to the **cys-Z** form takes place in a time which can be substantially longer than our simulation time. What we are really sampling here with the simulation is a state of the fluid that has not yet reached the chemical equilibrium completely. The agreement with the experimental data in the short range region (high  $Q$  values) however tells us clearly that the computations are able to grasp with great accuracy the positions of the electron-rich atoms, which, in turn, depend upon the isomerization state of the single molecules.

### 3.3 The [Ch][Asp] system

As in the previous case of [Ch][Cys], here we have two different de-protonation sites at the two carboxylic acid terminals. The complete deprotonation (as for the [Cys] IL) gives rise to a solid even above 90°. Partial deprotonation instead leads to a compound that has been shown to be a glassy solid slight above RT<sup>11</sup>, which turns into a viscous liquid at 90°. The first acid group deprotonated is the most acidic one (pKa=2.1) in the  $\alpha$  position; the second acid has a pKa=3.9. While in the previous case of [Ch][Cys] the additional protic function was a base, in this case we have an acid that has a much greater chance of donating protons. It has to be kept in mind however that the basicity and acidity scales in ILs differ significantly from those in water owing to the radically different microscopic structure of the medium and its lower polarizability (hence the lower dielectric constant with respect to water).

There are two ways in which the proton can be transferred between the anions. The first one takes place between a carboxyl and a carboxylate function, while the second sees the transfer from a carboxyl to an ammino group. What we have seen in our simulations is the occurrence of the second mechanism.

We begin our analysis of the AIMD trajectory by looking at the RDFs of the possible H-bond contacts and of the center of mass (c.o.m.) of the molecular ions that are both reported in Figure 6. If we look at the right panel we can see that in the case of [Ch][Asp] the average distance between the c.o.ms of the anions (black line) is comparable to the average distance between the anions and the cations (blue line) or even lower. The average distance between cations is instead larger than the other two. In [Ch][Asp] we have again a situation where the “typical” IL structure characterized by a charge-alternating pattern of ions is heavily modified by the presence of strong H-bonds that connect the anionic moieties. These connections, that may promote intramolecular proton transfer, are exclusively located between anions whereby the cations play a limited role and act here as mere spectators.

In the left panel of Figure 6, we have plotted the relevant RDFs for the geometric characterization of the complex H-bonding patterns. Most of the H-bonding features (blue line) connect the anions to the cations with an average C(O)O<sup>-</sup>... (H)—O distance of

2.7 Å. Two other kinds of H-bonds are present: the first one (black line) is formed between two anions and connects the carboxylate oxygen atoms to themselves; the second (red line) connects the carboxylate oxygen atoms to the nitrogen of the amino-group. Among the possible O-N contacts we have shown in the inset the two contributions due to the protonated and deprotonated carboxylate. As we see, the protonated carboxylate is the dominant configuration that is the one corresponding to a  $\text{C}(\text{O})\text{O}-\text{H}\cdots\text{N}$  arrangement. This is an important point because it shows how in these systems the amino-group acts as almost exclusively an **acceptor** of H-bonds and only marginally acts as a **donor** towards the negatively charged carboxylate.

Before proceeding to a discussion of the dynamics of protons ion the simulation, we highlight the fact that during the time span of the simulation we do not see any intramolecular proton transfer. All the proton transfers that we have found are between different anions and in particular we have that in 4 anion-anion pairs (over a total of 16, i.e. the 25% of the anions) a proton is transferred from the carboxylate to the amino-group. In this respect this liquid turns out to be radically different from the [Cys] based one and also a more promising candidate for proton conduction.

As an example, we have plotted the O—H and N—H distances for two inter-anionic proton transfer occurrences in Figure 7. As we see in both cases we have an initial situation where the proton is on the  $\text{COO}^-$  group and ends on the  $\text{NH}_2$  group. The situation depicted by the upper panel is particularly interesting because, as shown by the corresponding snapshot sequence in Figure 8, we have an initial situation (frame 1) where the anion interacts with the deprotonated  $\text{COO}^-$  group of another [Asp] anion. Proton transfer does not occur between the carboxylates (as expected from pKa values), but the anion undergoes a rotation/displacement and the proton is finally transferred to the amino-group.

One of the most interesting cases of proton transfer is represented by the configurations sequentially depicted in Figure 9 where we show the situation of three anions connected through H-bonds and where there is the simultaneous transfer of two protons between them. Initially (frame 1) the two protons are on the carboxyl groups. In frame 2 they are transferred simultaneously to the  $\text{NH}_2$ . In frame 3 and 4 we see the reaction has completed.

The structure of the [Ch][Asp] IL is particularly intriguing as it results from our simulations because it seems to contain chains of anions interconnected by H-bonds along which proton transfer might occur quickly through jumps that are analogous to the “Grotthus” mechanism in water. The cation acts as a mere spectator.

### 3.4 [Ch][Asp] Experimental validation

The experimental and computed  $I(Q)M(Q)Q$  of the [Ch][Asp] system are reported in Figure 10. From the data presented we clearly see that our simulation is able to grasp with very good accuracy the position of the heavy atoms (oxygen, carbon and nitrogen). Since in the hydrogen bonding network the heavy atoms distances are strongly dependent upon the proton positions we conclude that the simulation data presented above represent a very reliable description of the true fluid at least from the point of view of its average geometrical structure. The small mismatch in the first peak at low  $Q$  is due to the intrinsic difficulty in determining the density of the experimental sample.

## 4 Conclusions and perspectives

The [Ch][Cys] and [Ch][Asp] PILs have been analyzed by means of state-of-the-art computational techniques. We have clearly identified in those materials several occurrences of proton transfer reactions that occur within or between anions. In particular we have discovered that the molecular ions composing the [Ch][Cys] liquid can undergo an isomerization reaction mediated by an intramolecular proton transfer from the –SH to the amino-group. We have also shown that this isomerization reaction leads to a complex material where part of the anions is in an anion-zwitterionic form. This feature might be the microscopic driving force for the peculiar bulk state of analogous liquids where the amino-acid has a heteroatom in the side chain which turned out to have higher viscosities and densities with respect to the other amino-acids.

The [Ch][Asp] liquid, on the other hand, has clearly shown many occurrence of intermolecular proton transfer that take place through the strong H-bonds existing between the protonated carboxylic group and the amino one. These H-bonds not only can promote the charge transport, but bringing into close contact the anionic moieties, they

can alter significantly the common microscopic structure of ILs where normally anions and cations form a well defined charge-alternating pattern.

While generally, PILs are ionic liquids formed through a quantitative acid-base reaction, where the transferred proton permanently resides on the cationic moiety (the base), the system examined here have both shown the possibility to trigger additional proton exchange reactions by means of the protons attached to the amino-acid side chains. It is well known that PILs are good candidate as solvents for electrochemical devices. The possibility, for these material of representing a viable route to an ideal situation where protons can find ways of moving through the fluid independently of the much slower molecular ions is therefore extremely appealing for electrochemical application. As stated by Belieres and Angell “a dry proton conductivity mechanism is one of “holy grails” of electrolyte science.”<sup>20</sup> From our results we conclude that, although limited in extent, proton transfer mechanisms in neat, dry ionic liquids is possible and may open new routes in electrochemical applications where the need for high conductivity, stable non aqueous media is a key objective.
