Received 12 June 2009; revised 29 January 2010; accepted 17 February 2010; published 20 July 2010.

[1] Nominally anhydrous minerals in 46 peridotite xenoliths hosted by Cenozoic basalts from five localities (Fangshan, Penglai, Qixia, Changle, and Hebi) of the eastern part of the North China Craton (NCC) have been investigated by Fourier transform infrared spectrometry (FTIR). The water contents (H<sub>2</sub>O wt %) of clinopyroxene (cpx), orthopyroxene (opx), and olivine (ol) range from 27 to 223 ppm, 8 to 94 ppm, and ~0 ppm, respectively. On the basis of (1) the homogenous H<sub>2</sub>O content within single pyroxene grains and (2) the equilibrium partitioning of H<sub>2</sub>O between cpx and opx, it is suggested that the pyroxenes largely preserve the H<sub>2</sub>O content of their mantle source, although possible H loss during xenolith ascent cannot be excluded for ol. The recalculated whole-rock H<sub>2</sub>O contents, using mineral modes and assuming a partition coefficient of 10 for water between cpx and ol, range from 6 to 56 ppm (average of 23 ± 13 ppm). In combination with previously reported data, the recalculated whole-rock water contents of peridotite xenoliths (105 samples from 9 localities) hosted by Cenozoic basalts from the eastern part of the NCC range from 6 to 85 ppm (average of 25 ± 18 ppm). The Cenozoic lithospheric mantle of the eastern part of the NCC is therefore characterized by a low water content compared to continental lithospheric mantle worldwide represented by typical cratonic and off-cratonic peridotites (normally 40–180 ppm, with average values of 119 ± 54 ppm and 78 ± 45, respectively) and to oceanic mantle values (>50 ppm) inferred from MORB and OIB. Peridotite xenoliths have low-to-moderate spinel Fe<sup>3+</sup>/ΣFe (0.02–0.34) and whole rock ΔFMQ values (from –4.2 to 2.2, normally between –2.5 and 1.5), which are not correlated with pyroxene H<sub>2</sub>O contents. Therefore, the low water contents cannot have resulted from oxidation of the mantle xenoliths and may have been caused instead by heating from an upwelling asthenosphere flow that acted in concert with NCC lithospheric thinning during the late Mesozoic to early Cenozoic. If so, the present eastern NCC lithospheric mantle represents essentially relict ancient lithospheric mantle after the thinning event, rather than newly accreted and cooled asthenospheric mantle.

### 1. Introduction

[2] Although the main minerals of the lithospheric mantle (olivine, orthopyroxene, clinopyroxene, etc.) are nominally anhydrous, they still contain a significant amount of hydrogen (colloquially referred to as “water” because the contents are

calculated as H<sub>2</sub>O) [Bell and Rossman, 1992a]. The presence of water in mantle minerals greatly affects their physical (rheology, electrical conductivity, seismic velocity, and attenuation) and chemical (elemental diffusion, partial melting) properties and therefore those of their mantle domains [Hirth and Kohlstedt, 1996; Karato and Jung, 1998; Hier-Majumder et al., 2005; Hirschmann et al., 2005]. Peridotite xenoliths hosted by alkali magma are samples from the lithospheric mantle. Thus their water contents may provide information about the distribution of water in the lithospheric mantle [Bell and Rossman, 1992a, 1992b; Ingrin and Skogby, 2000; Peslier et al., 2002; Peslier and Luhr, 2006; Grant et al., 2007b; Yang et al., 2008; Li et al., 2008; Bonadiman et al., 2009; Peslier, 2010].

[3] The North China Craton (NCC) is one of the major cratons in eastern Eurasia and contains crustal remnants older

than 3.8 Ga [Liu *et al.*, 1992]. It experienced widespread lithospheric extension since the late Mesozoic, which resulted in the removal of a large portion (>100 km in thickness) of the lithospheric mantle [Menzies *et al.*, 2007, and references therein]. Regardless of the mechanism (delamination, thermal/chemical erosion, etc.), the prerequisite of such thinning is the weakness of the lithospheric mantle. Due to the significant effects of water on mantle rheology, studying the water content and distribution in the NCC lithospheric mantle should provide pertinent information on the mechanism and process of lithospheric thinning. Yang *et al.* [2008] reported water contents of peridotite xenoliths hosted by Cenozoic basalts from Nushan and Hannuoba in the NCC, while Bonadiman *et al.* [2009] reported data from peridotite xenoliths hosted by Cenozoic basalts from Panshishan and Lianshan, which are close to Nushan. In this paper, we present the water contents of 46 peridotite xenoliths hosted by Cenozoic basalts from five localities in the NCC. Using our data and those previously published [Yang *et al.*, 2008;

Bonadiman *et al.*, 2009], we will address the following questions: (1) how much water is stored in the NCC Cenozoic lithospheric mantle? (2) is there a relationship between the water content and the NCC lithospheric thinning?

## 2. Geological Background and the Studied Samples

### 2.1. Geological Background of the NCC

[4] On the basis of the lithological assemblage, tectonic evolution and P-T-t paths of metamorphic rocks, the North China Craton is divided into the Western and Eastern blocks, separated by the Trans-North China Orogenic Belt (Figure 1) [Zhao *et al.*, 2000; 2001]. The Western Block is composed of late Archean to early Proterozoic metasedimentary belts that unconformably overlie the Archean basement; the latter consists mainly of granulite facies gneiss and charnockite with small amounts of mafic granulites and amphibolites. The basement of the Trans-North China Orogenic Belt consists of late Archean amphibolites and granulites, and 2.5 Ga granite-greenstone terrains. It is overlain by 2.4–2.2 Ga bimodal volcanic rocks in the southern region and thick carbonate and terrigenous sedimentary rocks inter-layered with thin basalt flows in the central region. The Eastern Block is composed of late Archean orthogneisses intruded by 2.5 Ga syntectonic granitoids. The collision between the Western and Eastern blocks at 1.8–2.0 Ga ago may have led to the formation of the Trans-North China Orogenic Belt and represents the final amalgamation of the North China Craton.

[5] The North China Craton experienced a widespread tectonothermal reactivation in the Phanerozoic, marked by the emplacement of Early Paleozoic kimberlites, extensive late Mesozoic granites and intermediate to mafic intrusions, and Cenozoic basalts [Menzies *et al.*, 2007, and references therein]. Ultramafic xenoliths from the Paleozoic diamond-bearing kimberlites are highly refractory deep-seated garnet-facies peridotites. They represent a typical ancient cratonic lithospheric mantle, which was thick (~200 km) and cold (geotherm ~40 mW/m<sup>2</sup>) at least until mid-Ordovician time [Zheng and Lu, 1999; Wu *et al.*, 2006; Zhang *et al.*, 2008]. In contrast, ultramafic xenoliths hosted by late Cretaceous and Cenozoic basalts are dominated by fertile spinel-facies peridotites, and represent a thin (60–100 km), hot (mean geotherm ~80 mW/m<sup>2</sup>) and compositionally heterogeneous lithospheric mantle [Fan and Hooper, 1989; Xu *et al.*, 1995; Xu *et al.*, 1998; Zheng *et al.*, 1998, 2001, 2006; Fan *et al.*, 2000; Rudnick *et al.*, 2004; Reisberg *et al.*, 2005; Ying *et al.*, 2006]. These observations suggest that more than 100 km of cratonic lithosphere was removed or strongly modified during late Mesozoic-early Cenozoic time [Menzies *et al.*, 1993, 2007; Griffin *et al.*, 1998; Xu, 2001; Xu *et al.*, 2008; Zheng *et al.*, 2001, 2006; Gao *et al.*, 2002, 2004, 2008; Zhang *et al.*, 2002, 2008; Zhang, 2005, 2009; Wu *et al.*, 2003, 2006]. The mechanisms and tectonic driving forces responsible for the NCC lithospheric thinning have been intensely debated [Menzies *et al.*, 2007, and references therein].

### 2.2. Outcrops and Peridotite Xenoliths

[6] The investigated samples are spinel-facies peridotite xenoliths hosted by Cenozoic basalts from five localities of the eastern NCC (Figure 1). All of these xenoliths, Iherzo-

litic to harzburgitic in composition, are relatively fresh and well preserved, with sizes ranging from 3 to 30 cm. A brief description of each locality and the nature of the peridotite xenoliths is provided below.

### 2.2.1. Fangshan

[7] Together with Panshishan and Lianshan [Reisberg *et al.*, 2005; Bonadiman *et al.*, 2009], Fangshan (GPS coordinates 32°18'59.9"N and 118°59'07.3"E) is located in the Subei basin, Jiangsu province (Figure 1). Alkali basalts from Fangshan have K–Ar ages of about 9 Ma [Chen and Peng, 1988]. Numerous big (up to 30 cm in diameter) and fresh peridotite xenoliths are hosted by these basalts; they are all spinel-facies peridotites, dominantly spinel lherzolites with rare spinel harzburgites. The 17 samples are coarse grained and mostly protogranular or porphyroclastic. Olivine (ol) and orthopyroxene (opx) are large (4–7 mm), while clinopyroxene (cpx) and spinel (sp) are smaller (1–3 mm). No hydrous minerals have been found.

### 2.2.2. Penglai

[8] Penglai volcano of Shandong province is located in the northeast part of Shandong Peninsula (Figure 1). Xenoliths occur in alkali basalts with 8 Ma K–Ar ages [Liu *et al.*, 1990]. A set of coarse-grained spinel lherzolites from this locality (GPS coordinates of the outcrop are 37°46'42.2"N and 120°44'46.4"E) has been investigated. No hydrous minerals were found in Penglai xenoliths.

### 2.2.3. Qixia

[9] The Qixia volcano is located in Shandong province about 50 km south of Penglai (GPS coordinates 37°12'15.5"N and 120°43'23.8"E) (Figure 1). Six spinel lherzolites with coarse-grained or fine-grained textures hosted by ~6 Ma olivine nephelinites [Liu *et al.*, 1990] were collected. No hydrous minerals have been found in these peridotites.

### 2.2.4. Changle

[10] The Changle volcano erupted in Shandong province, in the proximity of the Tan-Lu fault (Figure 1). Peridotite and websterite xenoliths and pyroxene and corundum megacrysts are found mainly in the 18–16 Ma and 10–9 Ma alkali basalts [Jin, 1985]. Five anhydrous, coarse-grained spinel lherzolites and one spinel harzburgite were investigated. The outcrop GPS coordinates are 36°37'11.5"N and 118°51'59.3"E.

### 2.2.5. Hebi

[11] The Hebi volcano (GPS coordinates 35°47'10.1"N and 114°12'34.7"E) of Henan province erupted ~4 Myr ago [Liu *et al.*, 1990]. Olivine nephelinites contain abundant small mantle xenoliths (1–5 cm in diameter) and garnet and pyroxene megacrysts. Hebi xenoliths are mainly refractory harzburgites with minor spinel lherzolites [Zheng *et al.*, 2001]. On the basis of major element compositions and in situ sulfide Re–Os isotope analysis of harzburgite xenoliths [Zheng *et al.*, 2001, 2006], Hebi is the only locality in the NCC with evidence of Archean relict mantle. All of the nine xenoliths studied are spinel harzburgites except for HB64, which is a spinel lherzolite.

## 3. Analytical Methods

### 3.1. Electron Microprobe

[12] The mineral compositions were determined using a JEOL Superprobe (JXA 8100) electron microprobe (EMP) at Nanjing University, China, with the following operating

conditions: 15 kV accelerating voltage, 10 nA beam current and <5 μm beam diameter. Natural minerals and synthetic oxides were used as standards, and a program based on the ZAF procedure was used for data correction. Multipoint measurements were carried out from the core to the rim of each mineral grain, and three to four grains of each mineral were measured in each sample.

### 3.2. Micro-FTIR

[13] Double-polished thin sections with a thickness ranging from 0.2 to 0.4 mm were prepared for FTIR analysis. Unpolarized spectra were obtained from 1000 to 5000 cm<sup>-1</sup> on a Nicolet 5700 FTIR spectrometer coupled with a Continuum microscope at the University of Science and Technology of China (USTC), using a KBr beam splitter and a liquid-nitrogen cooled MCT-A detector. For cpx and opx, a total of 128 or 256 scans were accumulated for each spectrum at a 2 or 4 cm<sup>-1</sup> resolution; for olivine up to 600 scans were accumulated. The aperture size was set from 30 × 30 to 100 × 100 μm, depending on the size and quality of the mineral grains. Measurements were made through optically clean, inclusion- and crack-free areas (usually the core region of selected grains) under a continuous dry N<sub>2</sub> gas flush.

[14] A modified form of the Beer-Lambert law was used to calculate the water content:

$$c = \Delta / (I \times t \times \gamma)$$

where  $c$  is the content of hydrogen species (ppm H<sub>2</sub>O wt %),  $\Delta$  is the integrated area (cm<sup>-2</sup>) of absorption bands in the region of interest,  $I$  is the integral specific absorption coefficient (ppm<sup>-1</sup> cm<sup>-2</sup>),  $t$  is thickness (cm), and  $\gamma$  is the orientation factor discussed by Paterson [1982]. OH absorption bands were integrated between 3000 and 3800 cm<sup>-1</sup> for cpx and 2800 to 3800 cm<sup>-1</sup> for opx to obtain  $\Delta$  values; the integral specific coefficient of 7.09 ppm<sup>-1</sup> cm<sup>-2</sup> for cpx and of 14.84 ppm<sup>-1</sup> cm<sup>-2</sup> for opx were used [Bell *et al.*, 1995] to calculate H<sub>2</sub>O content; thickness was measured using a digital micrometer and reported as the average of 30–40 measurements covering the whole section; an orientation factor of 1/3 was used in the calculation for cpx and opx [Paterson, 1982]. Baseline corrections were carried out by hand at least three times for each spectrum, the uncertainty was less than 5% and the average corrected spectrum was used to calculate water content. To minimize possible uncertainties from the unpolarized determination of these optically anisotropic minerals, more than 15–20 different grains of each mineral (more than 25 grains for ol) in the same sample were analyzed, and the average value was used to define the water content of that mineral in that sample [Asimow *et al.*, 2006; Grant *et al.*, 2007b; Kovacs *et al.*, 2008]. Uncertainties in the calculated water contents come from (1) using unpolarized infrared beams on unoriented minerals (<10%); (2) baseline correction (<5%); (3) variable sample thickness (<3%); and (4) differences between the absorption coefficients (<10%) of our samples and those of samples used by Bell *et al.* [1995] due to differences in composition. The total uncertainty is estimated to be less than 20–30%.

[15] Detailed FTIR profile analysis performed at the USTC lab of two augite megacrysts hosted by Nushan Cenozoic basanites confirmed the homogeneity of their water contents. These were used as standards to detect potential

<sup>a</sup>Mg # = 100 Mg/(Mg + Fe). Panshishan and Lianshan samples are also included because no olivine data have been given by *Bonadiman et al.* [2009].

instrument drift during analysis. During the analytical period including all of the NCC peridotites, the maximum variation for the two augites was <4% both for peak height and integrated area within the OH absorption area. The augites were also analyzed at the LMTG lab (Toulouse, France). The maximum difference of peak height and integrated area within the OH absorption area between the USTC and the LMTG labs was <3% during these crosscheck analyses.

## 4. Results

### 4.1. Mineral Chemistry and Thermometry

[16] The EMP analyses demonstrate the chemical homogeneity of the samples, with no variations observed among different grains of the same mineral of a given sample. The average values for ol, cpx, opx and sp. are reported in Tables 1–4. Our results are similar to the previously reported data for these localities [*Fan and Hooper*, 1989; *Zheng et al.*, 1998, 2001; *Rudnick et al.*, 2004]. Mg numbers (Mg # = 100 Mg/(Mg + Fe)) of ol from Fangshan, Penglai, Changle, and Qixia range between 88.7 and 91.2, typical for off-craton spinel peridotite xenoliths [*Gaul et al.*, 2000] and lower than those of cratonic peridotites (typically >92 with an average of 92.8 [*Bernstein et al.*, 2007]). The Hebi harzburgites are highly refractory with Mg # of ol ranging between 91.9 and 92.7, similar to those reported by *Zheng et al.* [2001]. One spinel lherzolite (HB64) is relatively fertile, with an ol Mg # of 87.9.

[17] Both experimental studies [e.g., *Jaques and Green*, 1980] and natural samples [e.g., *Arai*, 1994] show that Mg # of ol and Cr # (= 100Cr/(Cr + Al)) of sp. progressively increase in peridotite residues with increasing melt extraction. With the exception of sample HB64 from Hebi, Mg # of ol and Cr # of sp. of our samples define a positive trend (Figure 2), suggesting a partial melting process.

[18] Equilibrium temperatures are estimated using the Ca-in-opx geothermometer of *Brey and Kohler* [1990] at a pressure of 15 kbar (Table 5). These temperatures vary between 900 and 1150°C, in the range of those previously

reported for the NCC peridotites [*Fan and Hooper*, 1989; *Xu et al.*, 1995; *Zheng et al.*, 1998, 2001, 2006; *Chen et al.*, 2001; *Rudnick et al.*, 2004; *Xu and Bodinier*, 2004].

### 4.2. Hydrogen Species and Water Content

[19] All the analyzed pyroxene grains in these peridotite xenoliths exhibit several prominent absorption bands in the OH-stretching vibration region (3000–3800 cm<sup>-1</sup>). Representative infrared spectra are shown in Figure 3a for cpx and Figure 3b for opx. In contrast, most of the coexisting ol have no detectable OH peak; only a few grains from Fangshan and Changle display weak OH bands (Figure 3c).

[20] The IR absorption bands of pyroxenes can be divided into different groups: (1) cpx: 3600–3635 cm<sup>-1</sup>, 3510–3550 cm<sup>-1</sup>, 3445–3470 cm<sup>-1</sup>; and (2) opx: 3570–3595 cm<sup>-1</sup>, 3500–3525 cm<sup>-1</sup>, 3390–3415 cm<sup>-1</sup>, 3300–3315 cm<sup>-1</sup>. The positions of these absorption bands are similar to those reported in earlier studies, and interpreted as resulting from the vibration of structural OH [*Skogby and Rossman*, 1989; *Skogby et al.*, 1990; *Bell and Rossman*, 1992a; *Ingrin and Skogby*, 2000; *Peslier et al.*, 2002; *Grant et al.*, 2007b; *Yang et al.*, 2008; *Li et al.*, 2008; *Bonadiman et al.*, 2009; *Gose et al.*, 2009b]. The relative absorbancy of these bands varies among grains in a given sample due to their variable orientation of grains with respect to the IR beam direction. Hydrogen profile measurements performed on the larger pyroxene grains in each suite of samples show no obvious variations between core and rim regions (Figure 3d). For ol grains with weak OH absorption bands (Figure 3c), the main peaks are at 3572 cm<sup>-1</sup> and 3525 cm<sup>-1</sup>, typical of mantle olivine [*Bell and Rossman*, 1992a; *Berry et al.*, 2005; *Demouchy et al.*, 2006; *Peslier and Luhr*, 2006; *Grant et al.*, 2007b; *Li et al.*, 2008].

[21] The water contents (ppm H<sub>2</sub>O, wt %) measured in pyroxene are given in Table 5. H<sub>2</sub>O contents vary from 27 to 223 ppm for cpx (Fangshan, 41–177 ppm; Penglai, 27–59 ppm; Qixia, 70–158 ppm; Changle, 71–223 ppm; Hebei, 181 ppm) and from 8 to 94 ppm for opx (Fangshan, 21–74 ppm; Penglai, 8–25 ppm; Qixia, 32–59 ppm; Changle,

<sup>a</sup>Mg # = 100Mg/(Mg + Fe). Panshishan and Lianshan samples are also included because only Al<sub>2</sub>O<sub>3</sub> and MgO contents of clinopyroxenes of have been given by *Bonadiman et al.* [2009].

25–94 ppm; Hebei, 31–96 ppm). *Aubaud et al.* [2007], *Yang et al.* [2008] and *Bonadiman et al.* [2009] reported similar values for the NCC peridotites. The cpx and opx water contents are strongly correlated ( $R^2 = 0.89$ ) with a cpx/opx ratio of 2.29 (Figure 4a). Taking into account all the values measured on peridotites from the NCC [*Aubaud et al.*, 2007; *Yang et al.*, 2008; *Bonadiman et al.*, 2009; this study], this ratio is 1.97 ( $R^2 = 0.77$ , Figure 4b). These ratios agree well with the H partition coefficient between cpx and opx reported from both experimental and natural mantle samples [*Bell and Rossman*, 1992a; *Peslier et al.*, 2002; *Koga et al.*, 2003; *Aubaud et al.*, 2004, 2007; *Bell et al.*, 2004; *Grant et al.*, 2007b; *Tenner et al.*, 2009]. The water distribution in pyroxenes from the NCC peridotites thus achieved equilibrium in the mantle and was preserved during xenolith exhumation. The latter is confirmed by the homogeneous distribution of water within individual pyroxene grains revealed by core-rim profile analyses [*Yang et al.*, 2008; *Bonadiman et al.*, 2009; this study].

[22] In agreement with previous results from samples from Nushan, Hannuoba, Panshishan, and Lianshan from the NCC [*Aubaud et al.*, 2007; *Yang et al.*, 2008; *Bonadiman et al.*, 2009], ol grains in this study display very low water contents: only a few grains from Fangshan and Changle peridotites display weak OH absorption bands and the H<sub>2</sub>O contents are less than 2 ppm (Figure 3c). Because we used the average value of more than 25 ol grains for each peridotite to represent the water content of ol in that sample, H<sub>2</sub>O contents of ol in all samples are ~0 ppm even for those containing ol grains with ~2 ppm H<sub>2</sub>O. The water content of ol from spinel peridotite xenoliths hosted by alkaline basalts is typically lower than 10 ppm [*Bell and Rossman*, 1992a; *Peslier and Luhr*, 2006; *Grant et al.*, 2007b; *Gose et al.*, 2009a], due to possible initial low water contents or to possible H loss by diffusion during xenolith ascent to the surface [e.g., *Demouchy et al.*, 2006; *Peslier and Luhr*, 2006]. In contrast, pyroxenes coexisting with olivine appear to retain their initial H contents to a much larger extent [*Peslier et al.*, 2002; *Bell et al.*, 2004; *Grant et al.*, 2007b; *Yang et al.*, 2008; *Bonadiman et al.*, 2009; *Gose et al.*, 2009b]. In our case, the OH contents measured in ol (~0 ppm) cannot represent their source value. Instead, an initial H<sub>2</sub>O content can be calculated for ol by

considering equilibrium partitioning between pyroxenes and ol.

[23] The H<sub>2</sub>O partition coefficients between pyroxene and olivine determined by experiments are highly variable. The values obtained at low pressure (<3 GPa) are much higher than those at high pressure (>8GPa): At low pressures, *Koga et al.* [2003] obtained a value of  $12 \pm 2$  for Dopx/ol from a single experiment at P = 1.8 GPa; *Aubaud et al.* [2004] (revised according to the new calibration of *Aubaud et al.* [2007]) determined Dcpx/ol and Dopx/ol of  $28 \pm 2$  (n = 2) and  $14 \pm 2$  (n = 4), respectively, at P = 1–1.5 GPa; *Hauri et al.* [2006] reported Dcpx/ol and Dopx/ol of  $15 \pm 5$  (n = 5) and  $10 \pm 3$  (n = 8) respectively at P = 0.5–1.6 GPa; *Grant et al.* [2007a] determined Dopx/ol =  $25 \pm 1$  (n = 2) at P = 1.5 GPa; *Tenner et al.* [2009] obtained Dcpx/ol of 27 (n = 1) at P = 3 GPa. In contrast, at higher pressures, *Withers and Hirschmann* [2007] reported Dopx/ol of  $1.3 \pm 0.2$  (n = 4) at P = 8.0–12 GPa; and *Withers and Hirschmann* [2008] obtained Dopx/ol of  $1.5 \pm 0.2$  (n = 3) at P = 8.0 GPa. The difference between low-pressure and high-pressure experiments is probably related to reduced pyroxene Al content at P > 3 GPa (see data summarized in Figure 7 of *Hirschmann et al.* [2009]); it has been confirmed by experiments that Al could enhance water solubility in pyroxene (see data summarized in Figure 2 of *Hirschmann et al.* [2009]). *Grant et al.* [2007b] have shown that ol, opx and cpx from 8 peridotite xenoliths preserved the H<sub>2</sub>O contents of their mantle source and had Dcpx/ol values of  $88 \pm 48$  and  $22 \pm 24$  for spinel peridotites (P = 1.1–2.8 GPa) and garnet peridotites (P = 3.7–7.4 GPa), respectively.

[24] The NCC spinel lherzolite xenoliths hosted by Cenozoic basalts are from relatively thin lithospheric mantle (<80–100 km [*Menzies et al.*, 2007]), and the partition coefficient of H<sub>2</sub>O between pyroxene and olivine should be similar to those determined by low-pressure experiments (i.e., Dcpx/ol > 10 [*Koga et al.*, 2003; *Hauri et al.* 2006; *Aubaud et al.*, 2007; *Grant et al.*, 2007a; *Tenner et al.* 2009]). In the following, we use a Dcpx/ol = 10 to calculate the H<sub>2</sub>O content of coexisting ol; the calculated values should therefore represent maximum estimates. The recalculated whole-rock H<sub>2</sub>O contents based on mineral modes should also represent maximum estimates. These recalculated

<sup>a</sup>Mg # = 100Mg/(Mg + Fe). Panshishan and Lianshan samples are also included because only Al<sub>2</sub>O<sub>3</sub> and MgO contents of orthopyroxenes have been given by *Bonadiman et al.* [2009].

whole-rock H<sub>2</sub>O contents for the NCC peridotite xenoliths range between 6 and 85 ppm with an average value of 25 ± 18 ppm (Table 5).

## 5. Discussion

### 5.1. Preservation of Initial Water Content of the Mantle Source

[25] For  $P < 3.5$  GPa, the solubility of hydrogen in nominally anhydrous minerals (NAMs) increases with increasing pressure [*Keppler and Bolfan-Casanova*, 2006, and references therein; *Mierdel et al.*, 2007]; thus, when peridotite xenoliths are transported to the surface by their host magmas, hydrogen can potentially diffuse out the NAMs due to the sharp pressure fall. Diffusion experiments predict that at 1000°C hydrogen resetting in olivine and pyroxene will be achieved at millimeter scale in a few tens of hours [*Kohlstedt and Mackwell*, 1998; *Hercule and Ingrin*, 1999; *Carpenter et al.*, 2000; *Stalder and Skogby*, 2003]. In contrast, studies on natural samples suggest that pyroxenes preserve their mantle-derived OH contents, but ol do not [*Bell and Rossman*, 1992a; *Bell et al.*, 2004; *Peslier et al.*, 2002; *Grant et al.*, 2007b; *Gose et al.*, 2009b]. Possible explanations for the discrepancy may be related to the facts that (1) the loss of hydrogen is influenced by the water and oxygen fugacities of the systems and the H content of coexisting minerals and melt; (2) the incorporation of hydrogen into minerals does not only depend on the diffusion rate of hydrogen, but also on the diffusion rate of point defects associated with hydrogen incorporation, the latter being comparatively slower by at least several orders of magnitude [*Kohlstedt and Mackwell*, 1998]; and (3) experiments are made under H<sub>2</sub>O-saturated conditions, which probably do not prevail in natural systems.

[26] On the other hand, several lines of evidence suggest that pyroxenes of the NCC peridotites have largely preserved their initial water content in the mantle source.

[27] 1. H<sub>2</sub>O contents are homogeneous within individual pyroxene grains. Core-rim profile analysis for cpx and opx grains of the NCC peridotites [*Yang et al.*, 2008; *Bonadiman*

*et al.*, 2009; this study] have not revealed significant heterogeneities in H<sub>2</sub>O distribution within single grains, the latter normally being ascribed to diffusion.

[28] 2. H<sub>2</sub>O contents are positively correlated between cpx and opx. As shown in Figure 4, H<sub>2</sub>O contents of cpx and opx display a good positive correlation. The partition coefficient between cpx and opx (D<sub>cpx/opx</sub>) is 2.29 in considering only the data from this study, and 1.97 considering all the NCC data together. This is in the same range as the literature values reported for natural peridotite xenoliths: D<sub>cpx/opx</sub> = 2.3 ± 0.5 (n = 38 [*Bell and Rossman*, 1992a; *Peslier et al.*, 2002; *Grant et al.*, 2007b; *Li et al.*, 2008]), and also close to those determined by experiments using a low-blank SIMS method: *Aubaud et al.* [2004] reported D<sub>cpx/opx</sub> = 1.8 ± 0.3 [n = 1, the value is revised according to new calibration of *Aubaud et al.* 2007]; *Hauri et al.* [2006] obtained D<sub>cpx/opx</sub> = 0.9–1.4 (n = 6); *Tenner et al.* [2009] reported D<sub>cpx/opx</sub> = 1.2–2.0 (n = 3).

[29] On the basis of heterogeneous distribution of H<sub>2</sub>O within single grains (higher contents in the core and lower contents in the rim), several studies suggested significant loss of hydrogen in olivines by diffusion during xenolith ascent to the surface [*Demouchy et al.*, 2006; *Peslier and Luhr*, 2006; *Peslier et al.*, 2008]. Other studies did not observe any water heterogeneity in their olivines [*Bell et al.*, 2004; *Grant et al.*, 2007b]. We cannot address this issue based on the NCC olivines because their water contents are too low to be detected.

### 5.2. Comparison With Continental Lithospheric Mantle and Oceanic Mantle

[30] *Yang et al.* [2008] noticed that the Nushan and Hannuoba peridotites have much lower water contents than peridotites from cratonic and off-cratonic continental areas worldwide. Combining the previously published data [*Aubaud et al.*, 2007; *Yang et al.*, 2008; *Bonadiman et al.*, 2009] with our data, we obtain a total of 105 peridotites hosted by Cenozoic basalts from 9 localities of the eastern part of the NCC, which we use to make the following observations and interpretations. As described below, the

**Table 4.** Major Element Concentrations of Spinel From Peridotite Xenoliths Hosted by Cenozoic Basalts of the Eastern NCC<sup>a</sup>

<sup>a</sup>Cr # = 100 Cr/(Cr + Al). Panshishan and Lianshan samples are also included because no spinel data have been given by *Bonadiman et al.* [2009].

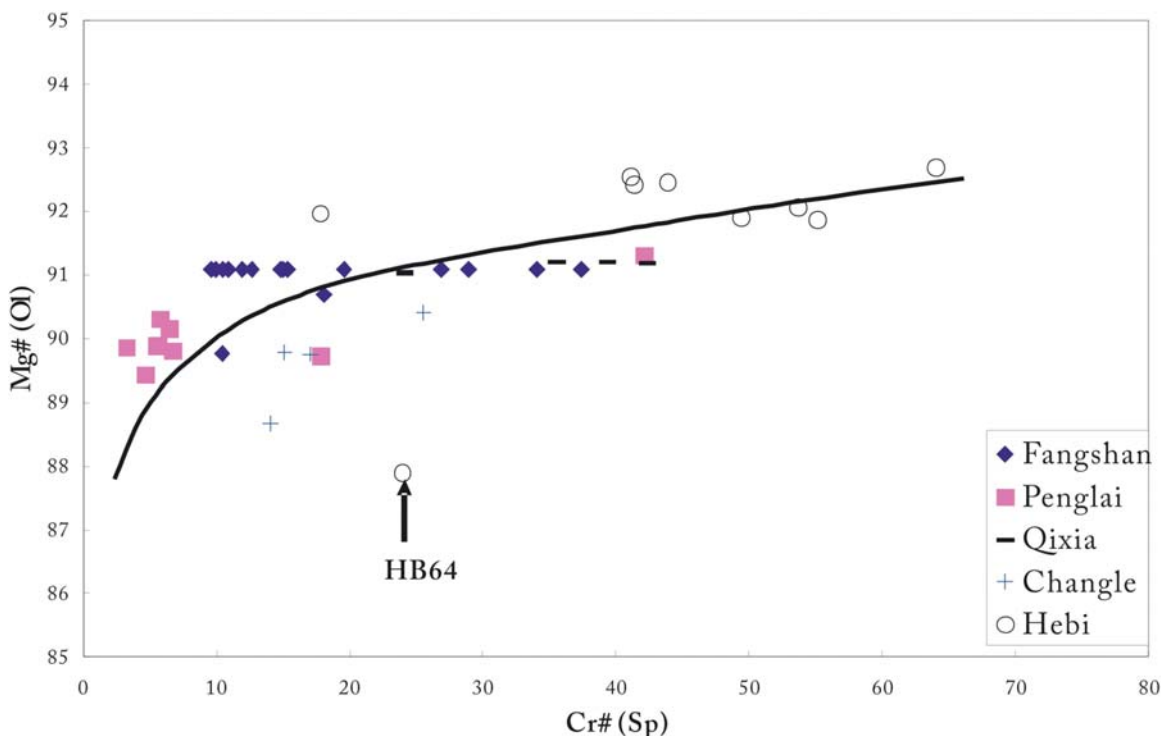

Cenozoic lithospheric mantle of the NCC (at least the eastern part) appears to have lower water contents compared to both the continental cratonic and off-cratonic lithospheric mantle worldwide and to the oceanic mantle.

### 5.2.1. Comparison With the Continental Cratonic and Off-Cratonic Lithospheric Mantle

[31] Water contents of peridotites from the NCC [*Aubaud et al.*, 2007; *Yang et al.*, 2008; *Bonadiman et al.*, 2009; this study] and other continental regions worldwide [*Bell and Rossman*, 1992a; *Peslier et al.*, 2002; *Demouchy et al.*, 2006; *Grant et al.*, 2007b; *Li et al.*, 2008; *Bonadiman et al.*, 2009] are compiled in Figure 5. On the basis of the geodynamic position of their sources, peridotite xenoliths in

other regions worldwide can be classified into two types: cratonic peridotite which is represented by South Africa and Colorado Plateau samples [*Bell and Rossman*, 1992a; *Grant et al.*, 2007b; *Li et al.*, 2008] and off-cratonic peridotite represented by Basin and Range (United States), Massif Central (France), Patagonia (Chile), and Antarctic samples [*Bell and Rossman*, 1992a; *Peslier et al.*, 2002; *Demouchy et al.*, 2006; *Grant et al.*, 2007b; *Li et al.*, 2008; *Bonadiman et al.*, 2009].

[32] Water contents of cpx of the NCC peridotites range between 5 and 355 ppm, with an average value of  $108 \pm 61$  ppm; 85 out of 92 samples contain less than 200 ppm H<sub>2</sub>O. In contrast, H<sub>2</sub>O contents of cpx from the cratonic peridotites

**Figure 2.** Mg # value of olivine versus Cr # value of spinel from Fangshan, Penglai, Qixia, Changle, and Hebi peridotite xenoliths of the NCC.

**Table 5.** Water Content, Mineral Mode, Temperature, Spinel  $\text{Fe}^{3+}/\Sigma\text{Fe}$  and  $\Delta\text{FMQ}$  of Peridotite Xenoliths Hosted by Cenozoic Basalts From the North China Craton<sup>a</sup>

Average <sup>c</sup>						108 ± 61	42 ± 27	25 ± 18			

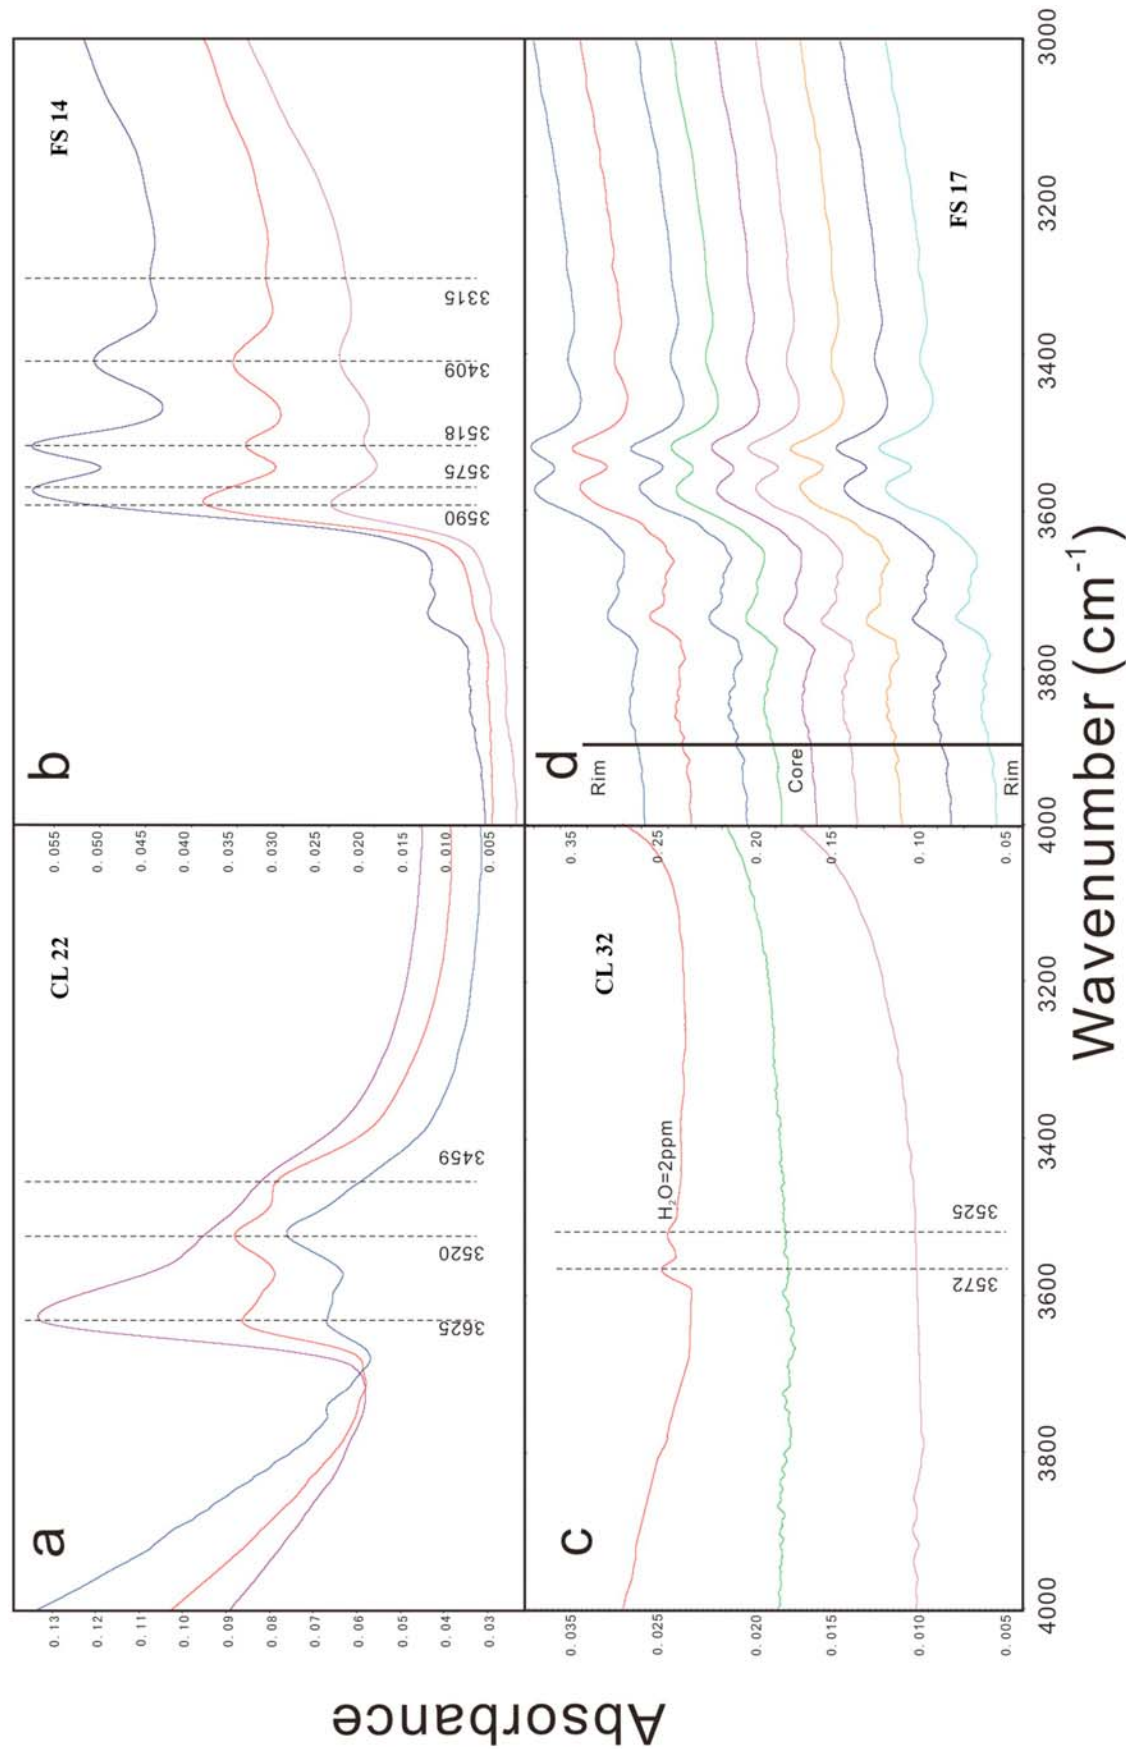

<sup>a</sup>H<sub>2</sub>O content of cpx and opx of the Nushan and Hannuoba samples is from Yang *et al.* [2008]; that of Panshishan and Lianshan is from Bonadiman *et al.* [2009]. The whole-rock (WR) H<sub>2</sub>O content were calculated by assuming Dcpx/ol as 10 to calculate olivine water content for all samples. Spinel Fe<sup>3+</sup>/ΣFe and ΔFMQ of Nushan, Hannuoba, Panshishan, and Lianshan samples were calculated by this study (see text). Some samples have not calculated ΔFMQ values because of different two-pyroxene geothermometers differed by 200°C or more (see text). Temperature for all T estimates on the basis samples were estimated by the Ca-in-opx geothermometer of Brey and Kohler [1990]. Cpx, clinopyroxene; opx, orthopyroxene; ol, olivine; sp, spinel; Lher, lherzolite; Harz, harzburgite.

<sup>b</sup>Average value of the new samples from this study.

<sup>c</sup>Average value of all the NCC samples. Mineral modes are estimated by point-counting method on one to three thin sections.

range between 370 and 950 ppm with an average value of 577 ± 209 ppm (397 ± 61 ppm if slab-influenced Colorado Plateau samples [Li *et al.*, 2008] are excluded), while those of cpx from the off-cratonic peridotites range between 5 and 528 ppm with an average value of 316 ± 151 ppm (Figure 5a).

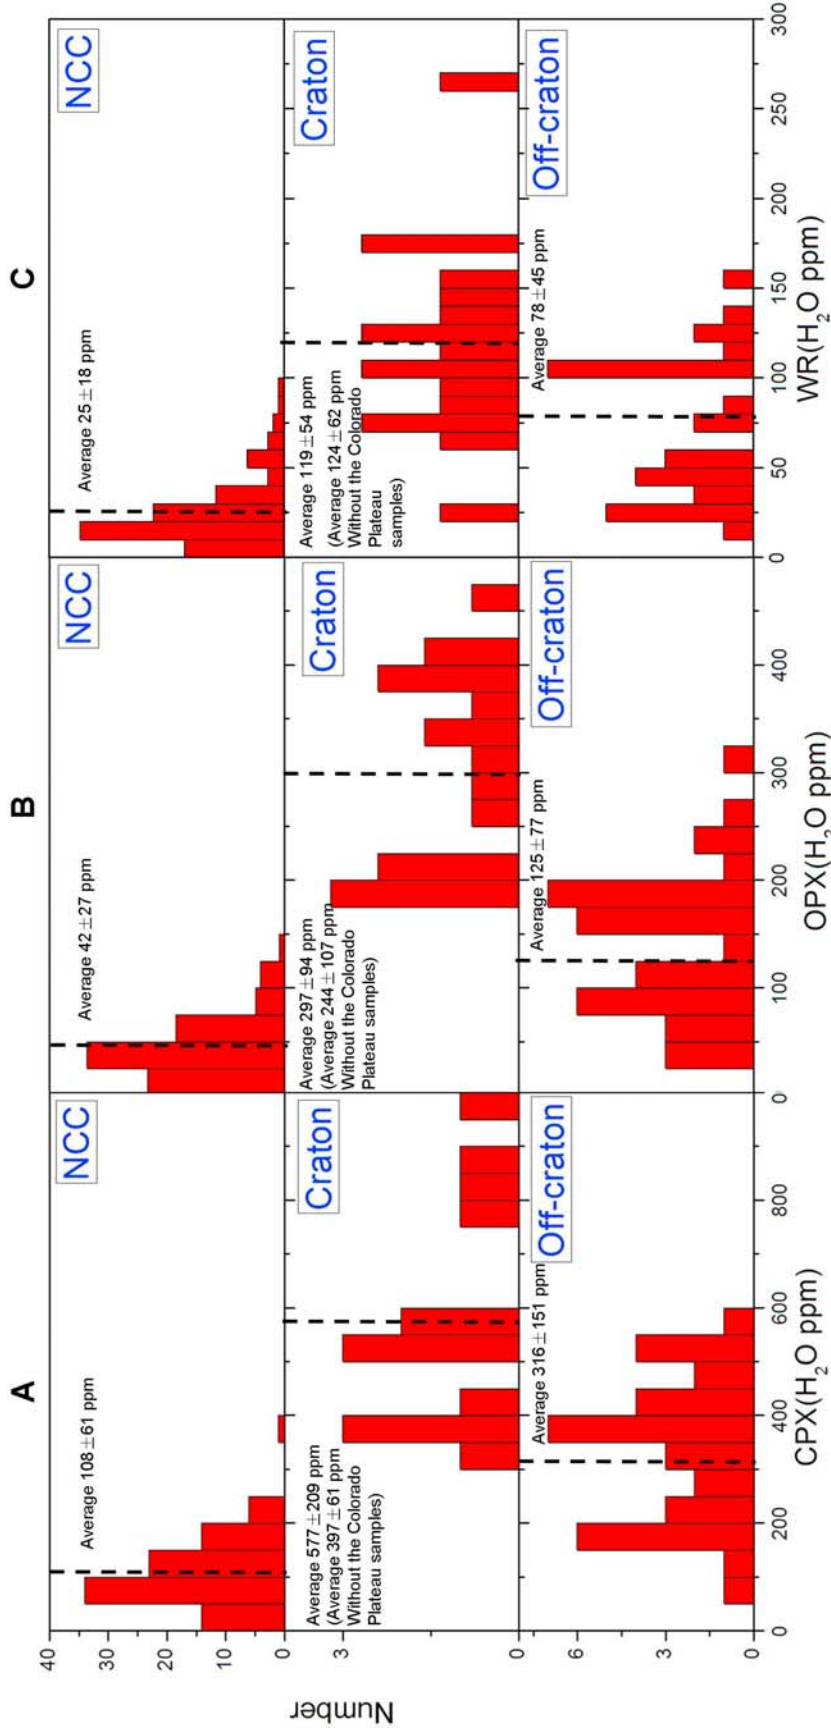

H<sub>2</sub>O contents of opx of the NCC peridotites range between 5 and 140 ppm, 96 out of 106 samples have less than 80 ppm and the average value is 42 ± 27 ppm. On the other hand, H<sub>2</sub>O contents of opx from the cratonic peridotites range between 180 and 400 ppm, with an average value of 297 ± 94 ppm

**Figure 3.** Representative IR spectra for (a) opx, (b) opx, and (c) ol of the NCC peridotites. Spectra of three grains from the same peridotite are shown. (d) A profile analysis for an opx grain from one Fangshan peridotite (FS17). The absorption at  $3740\text{ cm}^{-1}$  is an artifact of the instrument light; the weak  $3710\text{ cm}^{-1}$  peak is possibly due to subtraction of a background spectrum slightly contaminated by the presence of water vapor. The  $\text{H}_2\text{O}$  content of one olivine grain from Changle (CL32) is calculated on the basis of the absorption coefficient of *Bell et al.* [2003]. For clarity, all spectra were offset vertically. The thickness is 0.31, 0.29, 0.34, and 0.28 mm for CL22, FS14, CL32, and FS17, respectively.

**Figure 4.** Opx H<sub>2</sub>O content versus cpx H<sub>2</sub>O content for peridotite xenoliths (a) from this study and (b) from this study and samples from Nushan and Hannuoba reported by *Aubaud et al.* [2007] and *Yang et al.* [2008] and Panshishan and Fangshan from *Bonadiman et al.* [2009]. The dashed lines represent the experimental partition coefficients obtained by *Aubaud et al.* [2007], and the solid lines are the partition coefficients for natural peridotite xenoliths (n = 38 [*Bell and Rossman, 1992a; Peslier et al., 2002; Grant et al., 2007b; Li et al., 2008*]).

**Figure 5.** Comparison of H<sub>2</sub>O contents of cpx, opx, and whole rock (WR) of the NCC peridotite xenoliths with those of cratonic and off-cratonic peridotites. The NCC data are from *Aubaud et al.* [2007] and *Yang et al.* [2008] for Nushan and Hannuoba, *Bonadiman et al.* [2009] for Panshishan and Lianshan, and this study for Fangshan, Penglai, Qixia, Changle, and Hebi. The data for cratonic peridotites (South Africa and Colorado Plateau) are from *Bell and Rossman* [1992a], *Grant et al.* [2007b], and *Li et al.* [2008]; the data for off-cratonic peridotites (Basin and Range area, French Massif Central, Patagonia, Antarctic and West Kettle, British Columbia) are from *Bell and Rossman* [1992a], *Peslier et al.* [2002], *Peslier and Luhr* [2006], *Demouchy et al.* [2006], *Grant et al.* [2007b], *Li et al.* [2008] and *Bonadiman et al.* [2009]. For cratonic samples, two average values are given: with or without the Colorado Plateau samples which were rehydrated by a subduction slab [*Li et al.*, 2008].

( $244 \pm 107$  ppm if slab-influenced Colorado Plateau samples [Li *et al.*, 2008] are excluded), while those of opx from the off-cratonic peridotites range between 9 and 300 ppm, with an average value of  $125 \pm 77$  ppm (Figure 5b).

[33] Comparison of whole rock values indicates a pattern consistent with the pyroxene data. The estimated whole rock water contents (calculating H<sub>2</sub>O contents of ol by assuming  $D_{\text{cpx/ol}} = 10$  for all the samples) of the NCC peridotite xenoliths range between 6 and 85 ppm with an average value of  $25 \pm 18$  ppm. In contrast, those of cratonic peridotites are more than 60 ppm (except for one dunite from Colorado with 27 ppm) with an average value of  $119 \pm 54$  ppm ( $124 \pm 62$  ppm if slab-influenced Colorado Plateau samples [Li *et al.*, 2008] are excluded). Those of off-cratonic peridotites are between 10 and 154 ppm, with an average value of  $78 \pm 45$  ppm (Figure 5c).

[34] Only a few “off-craton” peridotites have water contents similar to those of NCC mantle xenoliths (Figure 6c). These harzburgite and dunite samples have experienced high degrees of partial melting [Peslier *et al.*, 2006; Li *et al.*, 2008; Bonadiman *et al.*, 2009]. As H<sub>2</sub>O behaves as a highly incompatible element during partial melting of a mantle source [Hauri *et al.*, 2006; Tenner *et al.*, 2009], the peridotite residues undergoing higher degrees of partial melting are expected to be more depleted in water. Moreover, lherzolites from San Carlos Cenozoic basalts have low water contents (171 to 178 ppm for cpx, 53 to 82 ppm for opx, and 2 to 4 ppm for ol [Li *et al.*, 2008]) similar to those of the NCC lherzolites. The low water contents of these rocks have been interpreted to result from water loss during partial melting [Li *et al.*, 2008].

### 5.2.2. Comparison With the Oceanic Mantle

[35] The available data for oceanic peridotites are very scarce. Peslier *et al.* [2007] analyzed three abyssal peridotites from Gakkel ridge, Arctic Ocean; the H<sub>2</sub>O contents are <1–5 ppm for ol, 25–60 ppm for opx, and 130–200 ppm for cpx. The low water contents of these samples are likely the consequence of water loss during the slow adiabatic decompression; thus they do not necessarily represent the mid-oceanic basalt (MORB). Gose *et al.* [2009b] investigated a suite of abyssal peridotites from the Mid-Atlantic Ridge. The measured H<sub>2</sub>O contents of opx range between 160 and 270 ppm and are suggested to reflect the original mantle contents. This range is much higher than that of opx of the NCC peridotites which varied from 5 to 140 ppm (96 out of 106 samples have water contents <80 ppm; Figure 5b).

[36] In contrast to oceanic peridotites, the H<sub>2</sub>O contents of MORB and OIB have been well constrained from melt inclusions and glass [Dixon *et al.*, 1988, 1997, 2002; Michael, 1988, 1995; Stolper and Newmann, 1994; Sobolev and Chaussidon, 1996; Danyushevsky *et al.*, 2000; Nichols *et al.*, 2002; Saal *et al.*, 2002; Simons *et al.*, 2002; Wallace *et al.*, 2002; Asimow *et al.*, 2004; Seaman *et al.*, 2004; Workman *et al.*, 2006]. On the basis of these data, the H<sub>2</sub>O contents of the sources of MORB and OIB are calculated to be about 50 to 250 ppm [Dixon *et al.*, 1988; Michael, 1988; Sobolev and Chaussidon, 1996; Saal *et al.*, 2002; Simons *et al.*, 2002; Asimow *et al.*, 2004] and between 300 and 1000 ppm, respectively [Dixon *et al.*, 1997; Wallace *et al.*, 2002; Nichols *et al.*, 2002; Simons *et al.*, 2002; Seaman *et al.*, 2004; Workman *et al.*, 2006]. Consequently, the H<sub>2</sub>O contents of the

NCC peridotites are lower than those of the oceanic mantle represented by the sources of MORB and OIB.

### 5.3. Possible Role of Redox State on Water Content

[37] On the basis of the negative correlation between water content of pyroxenes and oxygen fugacity for Mexican and Simcoe (Washington) spinel peridotite xenoliths, Peslier *et al.* [2002] suggested that pyroxene water contents are mainly controlled by the redox state of peridotites. In order to test this model in the NCC peridotites, we calculated the spinel  $\text{Fe}^{3+}/\Sigma\text{Fe}$  ratio and the peridotite oxygen fugacity (expressed as variation relative to the fayalite-magnetite-quartz oxygen buffer or  $\Delta\text{FMQ}$ ) based on EMP data from Yang *et al.* [2008] and from this study.  $\text{Fe}^{3+}$  values for spinels were calculated following the equation:  $\text{Fe}^{3+} = 8 - (4\text{Ti} + 3\text{Al} + 3\text{Cr} + 2\text{Fe} + 2\text{Mn} + 2\text{Ni} + 2\text{Mg})$  using atomic formula units normalized to three cations and discarding negative values.  $\Delta\text{FMQ}$  values were calculated following the protocol of Woodland *et al.* [1992]. A pressure of 15 kbar was assumed for all the samples. If the temperature estimates from two opx-cpx thermometers [Wells, 1977; Brey and Kohler, 1990] differed by 200°C or more, the samples were discarded for  $\Delta\text{FMQ}$  calculation. The overall uncertainty was empirically estimated to be  $\pm 0.5$  log units. The spinel  $\text{Fe}^{3+}/\Sigma\text{Fe}$  ratios and  $\Delta\text{FMQ}$  values are given in Table 5.  $\Delta\text{FMQ}$  values for the NCC peridotites vary from  $-4.2$  to  $+2.2$ , with most ranging between  $-2.5$  and  $+0.5$ . These values fall in the range of continental mantle as represented by peridotite xenoliths and peridotite massifs [Frost and McCammon, 2008, and references therein]. Spinel  $\text{Fe}^{3+}/\Sigma\text{Fe}$  values of the NCC peridotites vary from 0.03 to 0.34, with most values between 0.10 to 0.34, in the range of continental spinel peridotites (most of them range from 0.15 to 0.34 [Frost and McCammon, 2008, and references therein]) and the Mexican and Simcoe spinel peridotites [Peslier *et al.*, 2002]. Some of the NCC spinels have low  $\text{Fe}^{3+}/\Sigma\text{Fe}$  values, down to 0.03, and the majority of the NCC peridotites are not characterized by oxidized signatures ( $\Delta\text{FMQ} > 0$ ). In addition, no correlation between pyroxene H<sub>2</sub>O content and spinel  $\text{Fe}^{3+}/\Sigma\text{Fe}$  and peridotite  $\Delta\text{FMQ}$  values can be observed (Figure 6). Therefore, the low water content of the NCC samples cannot be related to high oxygen fugacity as has been argued in the case of the Simcoe peridotites [Peslier *et al.*, 2002].

### 5.4. Implications of the Low Water Content of the Eastern NCC

[38] The mechanisms responsible for lithospheric thinning of the NCC have been extensively debated [Menzies and Xu, 1998; Griffin *et al.*, 1998; Zheng *et al.*, 1998, 2001, 2006; Xu, 2001; Y. G. Xu *et al.*, 2008; Gao *et al.*, 2002, 2004, 2008; Zhang *et al.*, 2002, 2008, 2009; Zhang, 2005; Wu *et al.*, 2003, 2006; Niu, 2005; Menzies *et al.*, 2007]. Several models have been proposed, which can be grouped into two end-members: “top-down” rapid (<10 Ma) delamination models versus “bottom-up” protracted (possibly up to 100 Ma) thermomechanical-chemical erosion models. Delamination would have produced the removal of the entire lithospheric mantle and probably part of the lower crust [Wu *et al.*, 2003, 2006; Gao *et al.*, 2004, 2008]. Thus the resulting (present) lithospheric mantle beneath the NCC would be asthenospheric mantle, newly accreted and cooled during the late Mesozoic-early Cenozoic thinning. On the other hand,

Figure 6. H<sub>2</sub>O content of cpx and opx versus Fe<sup>3+</sup>/ΣFe of spinel and ΔFMQ of peridotite from the NCC.

thermal erosion models predict that most of the present lithospheric mantle is composed of thinned, relict Archean-Proterozoic mantle [Griffin *et al.*, 1998; Menzies and Xu, 1998; Xu, 2001].

[39] According to the delamination model, the newly formed lithospheric mantle should be composed of essentially unmodified, cooled asthenosphere because there was no significant asthenosphere-derived basaltic magmatism associated with the NCC lithospheric thinning [Menzies *et al.*, 2007, and references therein]. If the delamination model is accepted, the water contents of the present lithospheric mantle should be similar to that of the source of MORB (50–250 ppm), which is not the case for the majority of the eastern NCC peridotites. Moreover, the fact that the NCC peridotites display water contents much lower than those of oceanic peridotites from the Mid-Atlantic Ridge [Gose *et al.*, 2009b] also argues against an asthenospheric source.

[40] Therefore, we suggest that the low water contents of the eastern NCC samples result from the reheating of the lithosphere from below by an upwelling asthenospheric flow that occurred in concert with lithospheric thinning. If so, most of the Cenozoic lithospheric mantle of the eastern NCC should be considered as relict ancient mantle after lithospheric thinning during the late Mesozoic-early Cenozoic. A few peridotite xenoliths from Nushan and Changle (Table 5) having H<sub>2</sub>O content greater than 50 ppm (up to 85 ppm) may actually represent newly accreted and cooled asthenospheric materials. This scenario is in agreement with the available age constraints from Re-Os isotopic data on peridotite xenoliths hosted by Cenozoic basalts from the eastern NCC (including whole rock and sulfides) [Meisel *et al.*, 2001; Gao *et al.*, 2002; Xia *et al.*, 2004; Reisberg *et al.*, 2005; Wu *et al.*, 2006; Zhi *et al.*, 2007; Y. G. Xu *et al.*, 2008; X. S. Xu *et al.*, 2008; Zhang *et al.*, 2009]. Using the Os proxy isochron (<sup>187</sup>Os/<sup>188</sup>Os versus Al<sub>2</sub>O<sub>3</sub> or Yb, etc.), the melting age of the eastern NCC lithospheric mantle is early Proterozoic to Mesoproterozoic. Taking into consideration the Re depletion model ages (T<sub>RD</sub>) of the most depleted samples of each area, we also obtain a Proterozoic age, which represents a minimum age for melt extraction.

## 6. Conclusions

[41] 1. The H<sub>2</sub>O contents of cpx, opx and ol of peridotite xenoliths hosted by Cenozoic basalts from the eastern part of the NCC (Fangshan, Penglai, Qixia, Changle, and Hebi) are 27–223 ppm, 8–94 ppm, and ~0 ppm respectively. The homogenous H<sub>2</sub>O distributions within single pyroxene grains and the equilibrium partitioning of H<sub>2</sub>O between cpx and opx support the proposition that the pyroxenes largely preserve their initial H<sub>2</sub>O contents, acquired in their mantle source. The recalculated whole-rock H<sub>2</sub>O contents, using mineral modes and assuming a partition coefficient of 10 for water between cpx and ol, range from 6 to 56 ppm, with an average of 23 ± 13 ppm.

[42] 2. In combination with previously reported data [Yang *et al.*, 2008; Bonadiman *et al.*, 2009], the whole rock water contents of peridotite xenoliths (105 samples from 9 localities) hosted by Cenozoic basalts from the eastern part of the NCC range from 6 to 85 ppm (average: 25 ± 18 ppm). The Cenozoic lithospheric mantle of the eastern part of the

NCC is therefore characterized by a low water content compared to worldwide continental lithospheric mantle represented by typical cratonic and off-cratonic peridotites (most of them range between 40 and 180 ppm, with average values of 119 ± 54 ppm and 78 ± 45 respectively) and to oceanic mantle (>50 ppm H<sub>2</sub>O inferred for the sources of MORB and OIB). This low water content is not related to the oxygen fugacity. We speculate that the low water content resulted from reheating by upwelling asthenospheric flow accompanying late Mesozoic to early Cenozoic lithospheric thinning. If this hypothesis is correct, the present eastern NCC lithospheric mantle mostly represents thinned, relict Archean-Proterozoic lithospheric mantle, rather than newly accreted, cooled asthenospheric mantle.
