Abstract

Although the importance of light for tomato plant yield and edible fruit quality is well known, the PHYTOCHROME INTERACTING FACTORS (PIFs), main components of phytochrome-mediated light signal transduction, have been studied almost exclusively in *Arabidopsis thaliana*. Here, the diversity, evolution and expression profile of *PIF* gene subfamily in *Solanum lycopersicum* was characterized. Eight tomato *PIF* loci were identified, named *SIPIF1a*, *SIPIF1b*, *SIPIF3*, *SIPIF4*, *SIPIF7a*, *SIPIF7b*, *SIPIF8a* and *SIPIF8b*. The duplication of *SIPIF1*, *SIPIF7* and *SIPIF8* genes were dated and temporally coincided with the whole-genome triplication event that preceded tomato and potato divergence. Different patterns of mRNA accumulation in response to light treatments were observed during seedling deetiolation, dark-induced senescence, diel cycle and fruit ripening. *SIPIF4* showed similar expression profile as that reported for *A. thaliana* homologs, indicating an evolutionary conserved function of PIF4 clade. A comprehensive analysis of the evolutionary and transcriptional data allowed proposing that duplicated *SIPIFs* have undergone sub- and neo-functionalization at mRNA level, pinpointing the importance of transcriptional regulation for the maintenance of duplicated genes. Altogether, the results indicate that genome polyploidization and functional divergence have played a major role in diversification of the *Solanum PIF* gene subfamily.

Introduction

Every aspect of plant physiology is influenced by light. Right after germination, etiolated growth (skotomorphogenesis) allows seedlings to seek for light at the soil surface and, upon light exposure, signal transduction initiates photomorphogenic development (deetiolation), characterized by chloroplast differentiation and initiation of photosynthetic activity. During autotrophic vegetative development, light provides the energy that fuels plant growth, designs architecture of mature plant and regulates flowering. Furthermore, light deprivation is an

Competing Interests: The authors have declared that no competing interests exist.

important senescence inducer in lower leaves shaded by upper leaves for nutrient remobilization. The capability to adjust to environmental light conditions is mediated by photoreceptors, which perceive and transduce light signals to the downstream transcriptional network that triggers adaptive responses [1].

Solanum lycopersicum, a fleshy fruit bearing species, is an excellent model for deciphering light signal transduction network. Firstly, because tomato plant yield and edible fruit quality are determined by plastid biogenesis and activity that, in turn, are highly dependent on light perception and transduction. *High pigment* tomato mutants, *hp1* and *hp2*, are deficient in the negative regulators of light signal transduction *DAMAGE DNA BINDING PROTEIN 1 (DDB1)* and *DE-ETIOLATED (DET1)*, respectively. The fruits of these plants show increased levels of chlorophyll and higher levels of the nutraceutical carotenoids, flavonoids and tocopherols in immature and mature stages, respectively [2,3]. Light-grown seedlings of tomato transgenic lines silenced for *ELONGATED HYPOCOTYL 5 (HY5)*, a positive regulator of light signaling involved in plastid biogenesis, displayed etiolated phenotype and adult plants showed over 30% reduction in leaf and immature fruit chlorophyll accumulation. Moreover, total carotenoid levels in ripe fruits of HY5-deficient plants were significantly decreased compared to wild type controls [4]. Secondly, *Solanum* lineage have been affected by two whole-genome triplications; the first occurred before the divergence between *Arabidopsis* and *Solanum* more than 120 MYA, while the second preceded the divergence between tomato and potato estimated at 71 (\pm 19.4) MYA [5]. Polyploidization events provide the basis for the evolution of novel functions and, in particular, the expansion of genes encoding transcription factors correlates with the evolutionary gain of morphological complexity [6]. In this sense, it has been proposed that these genome triplications contributed with fruit-specific functions in tomato, such as the ripening master transcription factor *RIPENING INHIBITOR (RIN)* and phytochrome (PHYs) photoreceptors that influence fruit quality [5].

PHYs are major photoreceptors that perceive red (R)/far-red (FR)-light. Five PHYs *loci* have been identified in tomato genome designated *PHYA*, *PHYB1*, *PHYB2*, *PHYE* and *PHYF* in accordance to the *A. thaliana* *PHYA* to *PHYE* homologs [7]. The role of the tomato PHYs in vegetative development has been explored by the characterization of mutants [8] and overexpressing [9] plants for *PHYA*, *PHYB1* and *PHYB2*. Increasing *PHYA* and *PHYB1* expression rendered mild effects on anthocyanin levels and on seedling and adult plant development. On the contrary, transgenic plants with high levels of *PHYB2* showed an acute inhibition of elongation, enhancement of anthocyanin accumulation, and strong amplification of the red light high irradiance response [9]. By using single, double or triple mutants (*phyA*, *phyB1*, *phyB2*, *phyB1B2*, *phyAB1* and *phyAB1B2*), a recent report evaluated the participation of different phytochrome species in the regulation of fruit development and ripening. The results showed that the impairment in distinct PHYs differentially influences the time intervals among fruit developmental stages as well as the carotenoid content [10].

PHYs exist in two different forms, the R-absorbing Pr form and the FR-absorbing Pfr form. R triggers activation of PHYs by converting the Pr form to the Pfr form, whereas FR inactivates Pfr converting it back to the Pr form. Active PHYs Pfr form is translocated to the cell nucleus where it physically interacts with the PHYTOCHROME-INTERACTING FACTORS (PIFs). PIFs are basic helix-loop-helix (bHLH) transcription factors that play a key role in PHY-mediated light signal transduction being part of the regulatory network of a wide range of developmental processes, from seed germination towards senescence. However, with few exceptions [11–14], PIFs have been only studied in *A. thaliana*. PIF proteins have an Active Phytochrome B-binding (APB) and a DNA-binding bHLH domain. The canonical PIFs, *i.e.* PIF1, PIF3, PIF4, PIF5 and PIF7, physically interact with PHYB; while PIF1 and PIF3 also interact with PHYA through an Active Phytochrome A-binding (APA) domain. Pfr-PIF interaction triggers

phosphorylation and subsequent proteasomal degradation of PIFs, which leads to physiological responses. A notable exception to this dynamic behavior is PIF7, which despite interacting with PHYB shows no detectable light-induced degradation [1]. Several target genes for *A. thaliana* PIF proteins have been identified. PIF3 mediates the initial phases of seedling light-induced chloroplast development during deetiolation through the regulation of nuclear genes involved in photosynthesis and chloroplast biogenesis [15]. ChIP-PCR experiment confirmed that PIF4 binds to the E-box motifs of the promoters of both chloroplast activity maintainer genes *GOLDEN 2-LIKE 1 (GLK1)* and *GLK2*, repressing their expression [16]. Additionally, PIF4 and PIF5 act as transcriptional activators of the master senescence transcription factor *ORESARA 1 (ORE1)* and chlorophyll degrading enzyme encoding genes, such as *STAY GREEN 1 (SGR1)* and *NON-YELLOW COLORING 1 (NYC1)*, during dark-induced senescence by direct interaction with the G-box motifs on the corresponding promoter regions [16–18]. Finally, PIF1 has been shown to directly bind the G-box motif of the promoter of the chlorophyll and carotenoid biosynthetic genes *PROTOCHLOROPHYLLIDE OXIDOREDUCTASE* and *PHYTOENE SYNTHASE (PSY)*, inducing and inhibiting their transcription, respectively [19,20]. Only one tomato *PIF* gene has been characterized so far, *PIF1a*, and, in agreement with its *Arabidopsis* ortholog showed to modulate carotenoid biosynthesis during fruit ripening. During green stages of fruit development, as a consequence of self-shading, Chl reduces R/FR ratio stabilizing PIF1a, which, in turn, represses the expression of the fruit-specific *PSY1*. After the onset of ripening, degreening allows the activation of Pfr and the consequent PIF1a degradation releases *PSY1* transcription, enhancing carotenogenesis [12, 21].

Considering the importance of light perception and signaling for plant development and fruit quality and, the poorly available knowledge about *PIF* genes in tomato; here we performed a comprehensive characterization of this gene subfamily in *S. lycopersicum*. By surveying the tomato genome, we identified eight *PIF* homolog sequences. The phylogenetic, divergence time estimation and selective pressure evaluation analyses allowed us to reconstruct the evolutionary history of *PIF* genes in *S. lycopersicum* and closely related Solanaceae species, the wild tomato *S. pennellii* and *S. tuberosum*. We further explored the transcriptional profile in four different developmental contexts, deetiolation, dark-induced senescence, daily cycle and fruit ripening, and identified expression patterns that suggest functional specificity. The data were discussed in the context of tomato genome evolution.

Results

Phylogenetic and Evolutionary Analysis of *PIF loci*

By performing a BLAST search against fully sequenced genome databases using *A. thaliana* canonical *PIF* sequences as queries, 119 sequences from 16 species were retrieved including sequences of the bHLH superfamily that do not belong to the *PIF* subfamily [1] (see [Material and Methods, S1 Table](#)). In agreement with previous report, no *PIF* homologs were found in chlorophytes [22]. In the basal land plants *Marchantia polymorpha* (liverwort), *Physcomitrella patens* (moss) and *Selaginella moellendorffii* (lycophyte), one, four and three *PIF* homologs were identified, respectively. Spermatophyte species harbor several gene copies that, based on the phylogenetic reconstruction, are mainly divided in two super clades named according to the corresponding *A. thaliana* homolog representative. The first contains PIF1 and PIF4 sequences and, the second encompasses PIF3, PIF3-like 1 and 2 (PIL1/2) [23], PIF8, PIF7, *ALCATRAZ (ALC)* and *SPATULA (SPT)* [24] sequences. In the second clade, PIF3 and PIL1/2, PIF7 and PIF8 and, ALC and SPT clustered together, respectively ([Fig 1, S1 Fig, S1 Text](#)).

Whereas *Arabidopsis* has six *PIF* encoding genes, henceforth named *AtPIFs*, eight *loci* were identified in *S. lycopersicum* genome, corresponding to the following accessions in Sol

Genomics Network database [25]: *SIPIF1a*: Solyc09g063010, *SIPIF1b*: Solyc06g008030, *SIPIF3*: Solyc01g102300, *SIPIF4*: Solyc07g043580, *SIPIF7a*: Solyc03g115540, *SIPIF7b*: Solyc06g069600, *SIPIF8a*: Solyc01g090790, *SIPIF8b*: Solyc10g018510 (Fig 1). Amino acid pairwise sequence alignments indicated that *Arabidopsis* and tomato homologs share 27–51% identity (S2 Table). Despite this low identity score, the APB-binding and bHLH domains were found in all tomato protein sequences, reinforcing their identity as PIF proteins. However, it is worth mentioning that tomato *SIPIF1b*, *SIPIF4* and *SIPIF8b* display an amino acid substitution in the APB-binding domain that alters the conserved Q residue to G, E and E, respectively [26]. On the contrary, APA-binding domain was exclusively identified in *SIPIF1s* and *SIPIF3* (S2 Fig). Interestingly, the tree topology clearly showed that *Arabidopsis AtPIF4* and *AtPIF5* genes were originated by a Brassicaceae exclusive duplication, explaining the existence of a single gene in tomato genome within the clade PIF4. No differences in gene copy number were observed between *S. lycopersicum* and the most distantly related species within Lycopersicon section (*i.e.* tomatoes), *S. pennellii*. For PIF1, PIF7 and PIF8 clades, the analyzed tomato species harbor two gene copies, while for PIF3 and PIF4 a single copy was identified. *S. tuberosum* has a similar *PIF* gene copy number, excepting for a single *PIF8* locus (Fig 1).

To gain insight on the evolutionary history of *PIF* gene family, we estimated the divergence time of *PIFs* using molecular clock [27]. The duplication of *PIF1*, *PIF7* and *PIF8* was estimated in a range of time from 59.2 to 91.2 MYA (millions of years ago). As expected [28,29], our data indicated that tomato and potato *PIF* genes diverged around the species splitting event (Fig 2) estimated about 5.1 to 7.3 MYA [30]; excepting *PIF7b*, for which an estimate of 22.5–23.8 MYA was retrieved. Similarly, the divergence of *S. lycopersicum* and *S. pennellii* *PIF* genes dates close to the estimated age of the most recent common ancestors within the species, 2.2–3.1 MYA [27], with the exception of *PIF8b*, for which a value of 6.2 MYA was obtained. The high divergence times

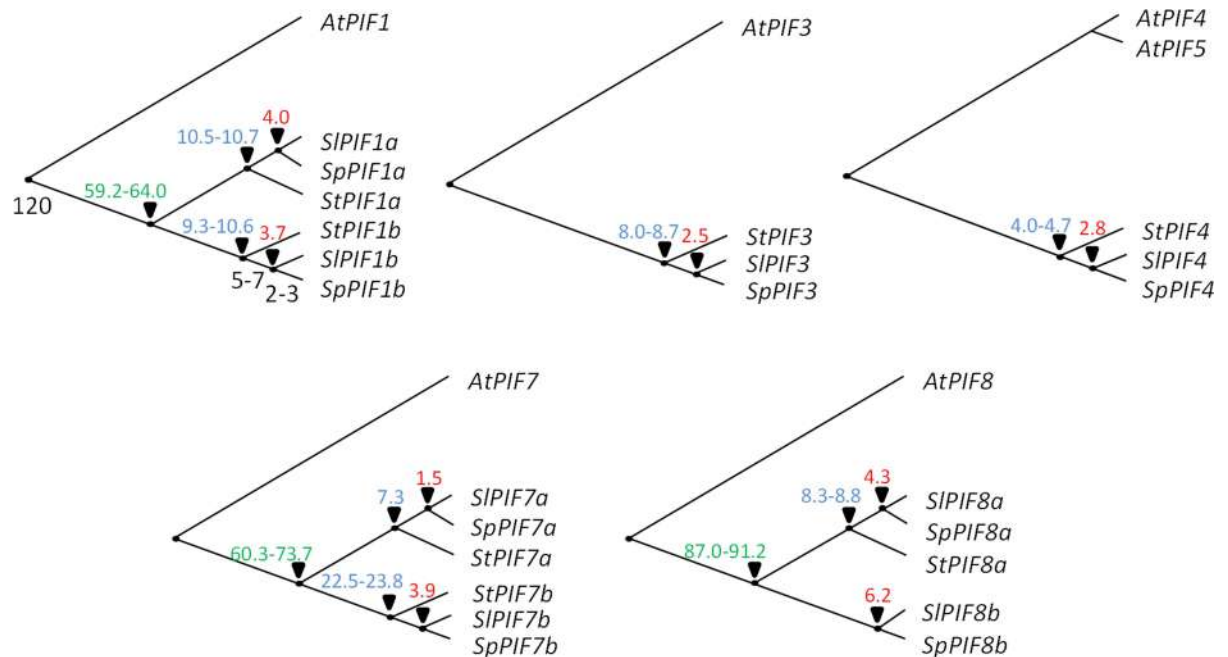

Fig 2. Divergence time estimations for *PIF* genes. The divergence times between the duplicated *PIF* genes in Solanaceae are shown in green. The divergence times between tomatoes (*S. lycopersicum* and *S. pennellii*) and *S. tuberosum* and, *S. lycopersicum* and *S. pennellii* homologs are indicated in blue and red, respectively. Species divergence times are shown in black (*Arabidopsis thaliana*-Solanaceae [34], *Solanum tuberosum*- *Solanum lycopersicum* [30], *S. pennellii*-*S. lycopersicum* [27]). Values are expressed in million years ago.

doi:10.1371/journal.pone.0165929.g002

observed for *PIF7b* and *PIF8b* are consequence of high synonymous substitution values (*dS*). Aiming to test whether the high *dS* values were consequence of positive selection or neutral evolution, we evaluated the selective constraints under which *PIF* gene are evolving (Table 1). Indeed, *PIF7b* showed signatures of positive selection, particularly in threonine 343 and serine 369 (BEB test $P > 95\%$). The rest of the *PIF* clades showed to be evolving under purifying selection. Unfortunately, we were unable to perform the test for *PIF8b* because it is absent in *S. tuberosum*.

PIF Transcript Profile along Seedling Deetiolation, Daily Cycle, Dark-Induced Senescence and Fruit Ripening

A. thaliana PIF proteins are known regulators of seedling deetiolation and dark-induced senescence, and are modulated by the circadian clock [1,17]. Particularly in *S. lycopersicum*, recently, the role of *SIPIF1a* in ripening-associated carotenogenesis was also been demonstrated [12]. To evaluate the functional diversity of tomato *PIF* genes, a comprehensive mRNA accumulation profiling was performed during seedling deetiolation, dark-induced senescence, diel cycle and fruit ripening. *SIPIF8a* and *SIPIF8b* were not considered for functional analyses because there are no publications demonstrating *A. thaliana* PIF8 and PHYs interaction, therefore, this clade was not considered a canonical PIF.

The expression profile of *SIPIF* genes during deetiolation was analyzed in 4 day-old dark-grown seedlings exposed to 24, 48 and 72 h of constant light or dark conditions. The dark-treated seedlings exhibited typical skotomorphogenic phenotype presenting long hypocotyls as well as closed, small and chlorotic cotyledons. Seedlings exposed to constant light underwent photomorphogenesis and showed shorter hypocotyls, opened apical hooks, expanded and green cotyledons and anthocyanin accumulation (S3A Fig). Cotyledon chlorophyll accumulation (S3B Fig) and mRNA levels of the chloroplast activity maintainer gene *SIGLK1* [31] (Fig 3) confirmed the skotomorphogenic and the photomorphogenic growth of the dark and light-treated seedlings, respectively. Light induced the expression of *SIPIF1a*, *SIPIF4* and *SIPIF7a*, whereas *SIPIF1b* and *SIPIF3* mRNA levels were significantly reduced upon light exposure. Interestingly, *SIPIF1* paralogs showed contrasting patterns of light regulation displaying an increase up to 5-fold for *SIPIF1a* and 4-fold for *SIPIF1b* after 72 h of light and dark treatment,

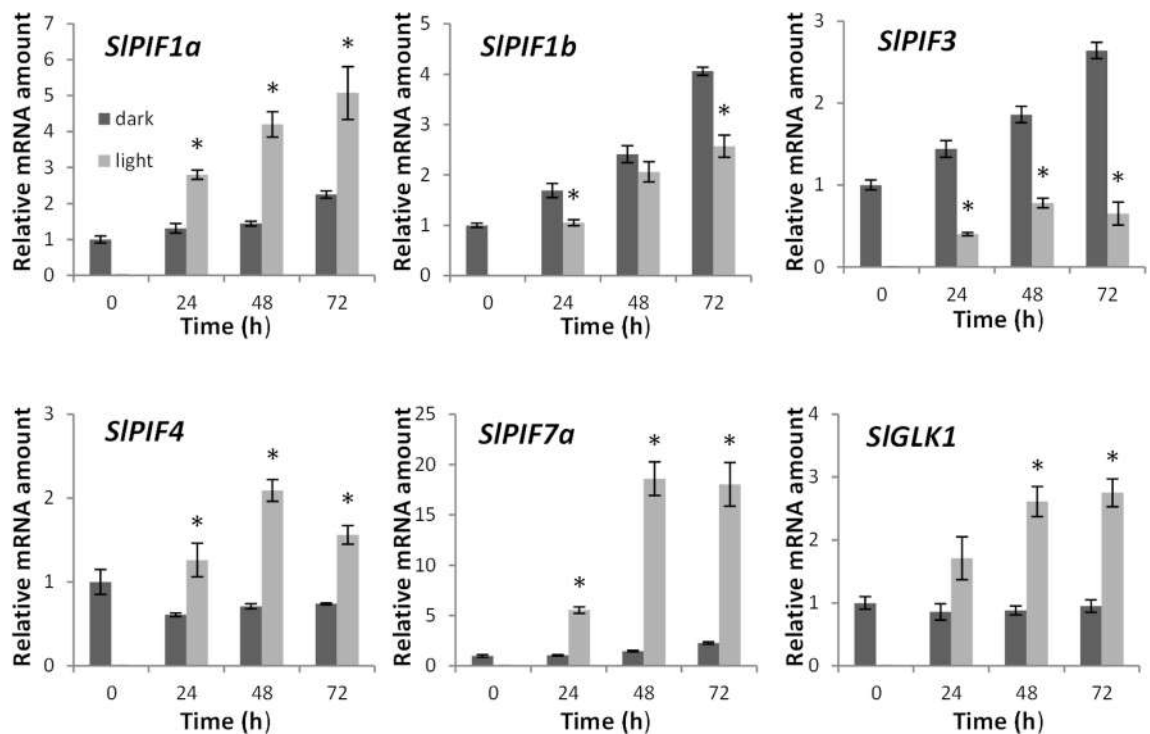

Fig 3. Expression profile of *PIF* genes in cotyledons under contrasting light conditions. Seedlings were grown in dark for 4 days and were either kept in darkness or transferred to continuous white light treatment. Significant differences ($P < 0.05$) among treatments are indicated by asterisks. Values shown are means \pm SE of at least three biological replicates.

doi:10.1371/journal.pone.0165929.g003

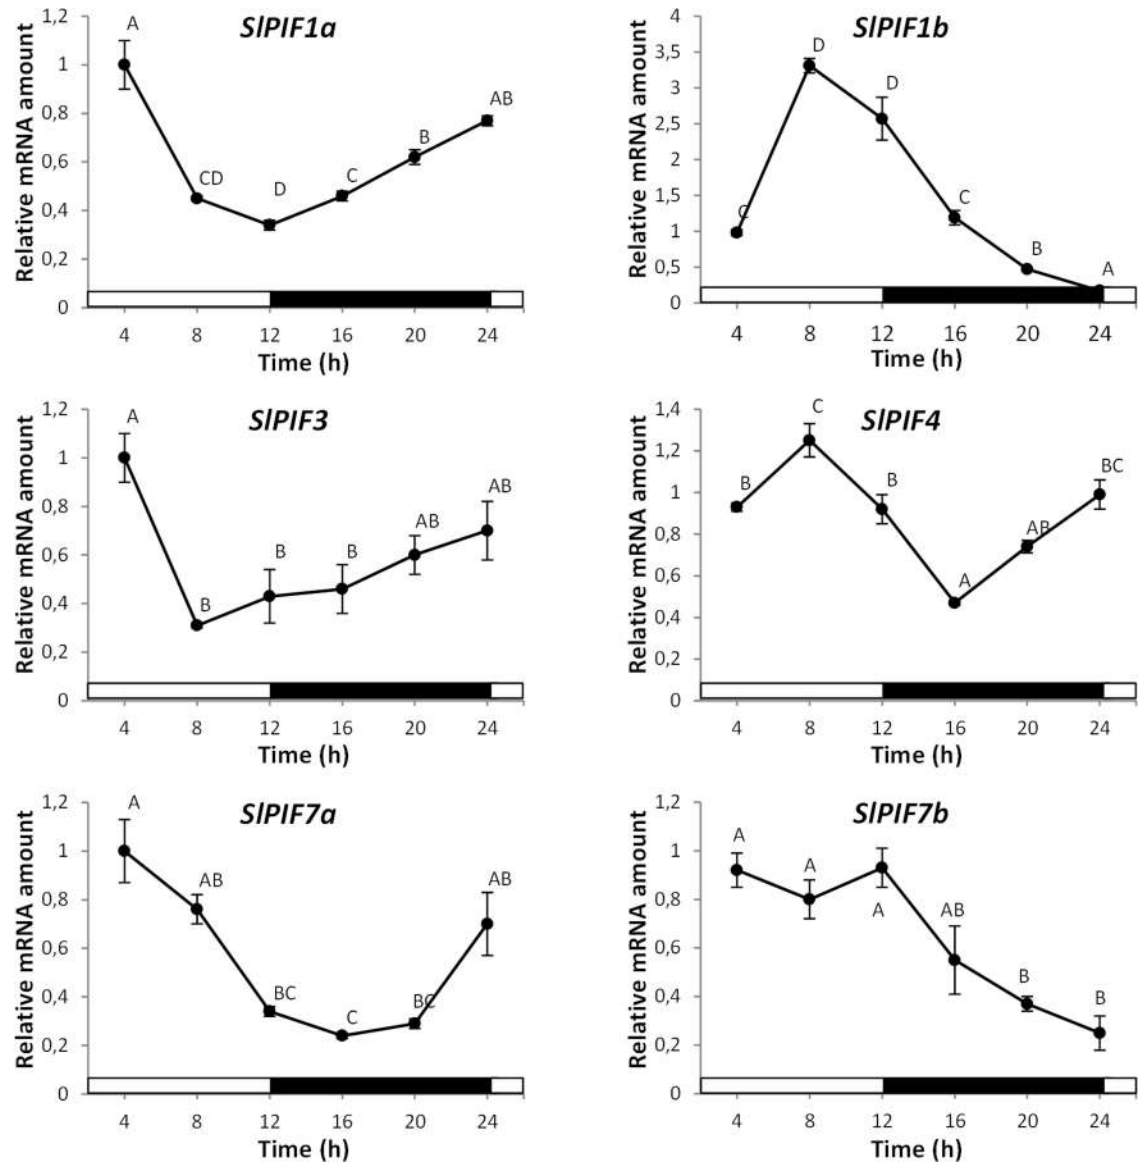

Fig 4. Expression profile of *PIF* genes during daily cycle. 3-week-old plants were grown under 12 h/12h light/dark photoperiod. The second fully expanded leaves were harvested every 4 h. White and black bars represent light and dark periods, respectively. Different letters indicate statistical differences ($P < 0.05$). Values shown are means \pm SE of at least three biological replicates.

doi:10.1371/journal.pone.0165929.g004

respectively. No significant transcript levels of *SIPIF7b* were detected in either treatment. A similar expression pattern of *SIPIF* genes was observed in the hypocotyls of light- and dark-treated seedlings (S3C Fig). It is worth noting that in terms of relative expression, *SIPIF1b* was the most abundantly *PIF* gene expressed in seedlings, both in cotyledons and hypocotyls. In cotyledons, *SIPIF4* showed intermediate mRNA levels followed by *SIPIF1a*, *SIPIF3* and *SIPIF7a*. In hypocotyls, *SIPIF4*, *SIPIF1a* and *SIPIF3* displayed similar intermediate amounts of transcript, while *SIPIF7a* was the least abundantly expressed (S3 Table).

The expression pattern of tomato *PIFs* during 24 h under 12/12 light/dark photoperiod was analyzed in 3-week-old plants (Fig 4). *SIPIF1a*, *SIPIF3* and *SIPIF7a* showed similar oscillation patterns, characterized by lowest transcript abundance at the end of the light period followed by a

progressive increase during the dark period and maximum levels 4 h after dawn. *SIPIF4* mRNA abundance was significantly reduced during the afternoon achieving the lowest level at dusk and progressively increasing over the night to reach the maximum level 8 h after dawn. *SIPIF7b* mRNA levels were high and constant during the light period, progressively decreasing during the night. *SIPIF1a* and its paralog *SIPIF1b* exhibited distinct diel expression patterns since during the night period *SIPIF1a* and *SIPIF1b* mRNA levels progressively increased and decreased, respectively. Interestingly, *SIPIF1* genes were the most copiously expressed *PIFs* at beginning of the light period displaying over 2-fold more transcripts in leaves than the other *PIF* genes (S3 Table).

Furthermore, we explored the transcriptional profile of *S. lycopersicum* *PIF* genes in leaves sampled from 3-week-old-plants maintained in darkness for 0, 1, 2, 3 and 7 days. The leaves showed clear signs of senescence as evidenced by the reduction in chlorophyll content at the seventh day (S4A Fig). The degreening was explained by the increment in *PHEOPHYTINASE* expression, the enzyme responsible for chlorophyll dephytylation in tomato leaves [32] and accompanied by a reduction in *SIGLK1* transcripts. Additionally, the induction of senescence was confirmed by the mRNA accumulation of the senescence marker *SENESCENCE-ASSOCIATED GENE 12* (*SISAG12*, [33]) and *A. thaliana* *ORE1* homologs *SIOR1S02*, *SIOR1S03* and *SIOR1S06* (S4B Fig). These data allowed us to conclude that after 7 days of dark treatment, the plants underwent dark-induced senescence. Transcriptional profiling revealed that *SIPIF1a*, *SIPIF3*, *SIPIF7a* and *SIPIF7b* were downregulated whereas *SIPIF1b* and *SIPIF4* were upregulated upon darkness exposure, suggesting that probably the formers are involved in dark-induced senescence signaling (Fig 5).

To address the transcriptional behavior of all six *SIPIF* genes during tomato fruit ripening and evaluate their possible involvement in the light-dependent regulation of this developmental process, fruits at mature-green (MG) stage were harvested and left ripen under constant light or dark conditions. Total chlorophyll and carotenoids levels were measured and, as expected a concomitant reduction in total chlorophylls temporally coincided with the accumulation of the main carotenoids typically found in tomato fruits, thereby demonstrating that the detached fruits were undergoing normal ripening (S5 Fig). The levels of transcripts for both *SIPIF7* paralogs were undetectable in all fruit stages analyzed. Under dark conditions, *SIPIF1a*, *SIPIF1b*, *SIPIF3* and *SIPIF4* mRNA levels peaked 2 days after the start of the treatment, when the fruits were still in MG stage, followed by a reduction at the breaker (BR) stage (Fig 6). During the progression of ripening, *SIPIF1a* showed to be transcriptionally induced and significantly higher in the presence of light, whereas the mRNA levels of its paralog, *SIPIF1b*, were clearly lower in light- than in dark-treated fruits and did not respond to ripening. Finally, *SIPIF3* and *SIPIF4* mRNA levels were relatively constantly low along ripening and did not show clear patterns of regulation by light and dark treatments. In terms of relative expression, the most abundantly expressed *PIF* gene in fruits was *SIPIF3*, with 17-, 6- and 1.7-fold more mRNA amount than *SIPIF4*, *SIPIF1a* and *SIPIF1b*, respectively (S3 Table).

Discussion

The key role played by light signaling on tomato plant development and fruit nutritional value has been widely studied by the use of mutants and transgenic approaches [3,4]. However, *PIF* genes have been lagged behind and almost exclusively studied in *A. thaliana* [11–14]. Besides the well described PHY-mediated proteasomal degradation mentioned above, *PIF* genes are under tight transcriptional regulation as indicated by database and genome-wide binding site analyses for several *A. thaliana* transcription factors. Moreover, it has been suggested that AtPIFs regulate their own expression by a complex autoregulatory mechanism [34], pinpointing the importance of studies approaching the expression regulation at transcriptional level.

Fig 5. Expression profile of PIF genes during dark-induced senescence. 3-week-old plants were grown under 12 h/12 h light/dark photoperiod and transferred to constant darkness during 7 d and the second fully expanded leaves was sampled every day 4 h after the beginning of the light period. Heatmap representation of the relative mRNA abundance compared to day 0. Different letters indicate statistical differences ($P < 0.05$). Values shown are means \pm SE of at least three biological replicates.

doi:10.1371/journal.pone.0165929.g005

Aiming to gain insights on the function of these genes in tomato, here we explored their genetic diversity and expression profiling along different physiological contexts.

PIF is one of the 26 gene subfamilies of the monophyletic bHLH superfamily of plant transcription factors [22]. By using the five well described PIF proteins sequences from *A. thaliana* as baits (*i.e.* AtPIF1/3/4/5/7), we retrieved 119 homologs from 16 species and performed a

Fig 6. Expression profile of PIF genes during ripening under contrasting light conditions. Fruits were harvested at MG (mature-green) stage and left to ripen under constant light or dark conditions. Pericarp samples were harvested at MG (two days after the beginning of treatment), BR (breaker), BR1 (1 day after BR), BR3, BR6 and BR12 stages. Asterisks and letters represent significant ($P < 0.05$) differences between treatments and stages, respectively. Values shown are means \pm SE of at least three biological replicates.

doi:10.1371/journal.pone.0165929.g006

phylogenetic analysis that allowed the identification of eight clades in Spermatophyte species (Fig 1). A comparative study between tomato and grape genomes proposed that a whole-genome triplication affecting Rosids, which includes *Arabidopsis*, and Euasterids, which includes *Solanum*, occurred in a common eudicot ancestor more than 120 MYA [5,35]. Interestingly, the monocot representatives of our phylogenetic reconstruction, *Oryza sativa* and *Sorghum bicolor*, did not show *PIF* genes in all the eight identified clades (Fig 1, S1 Table). Further, another triplication estimated at 71 (\pm 19.4) MYA occurred in the *Solanum* lineage followed by widespread gene loss that predates the 7.3 MYA tomato–potato divergence [5,30]. This second event was likely the origin of the duplications within PIF1, PIF7 and PIF8 clades since the estimated divergence time between the duplicated genes coincided with the date of the whole-genome triplication (Fig 2). To confirm this hypothesis, the gene collinearity was analyzed along the flanking genomic regions of the duplicated genes. As demonstrated for Solanaceae *PSY* genes [5], the *SIPIF1*, *SIPIF7* and *SIPIF8* paralog regions showed recognizable small scale synteny (S6 Fig). Thus, these polyploidization events may represent the foundation of the PIF subfamily diversification.

The evolutionary history of a genome is the result of the interdependent diversification of different genetic features like regulatory sequences, mobile elements and coding regions. Although, it is expectable that the gene divergence time approximately coincides with the corresponding species splitting date, heterogeneity in the nucleotide substitution rates among

genetic features within the genome can defy the molecular clock approach [36]. In this sense, the estimated divergence time for tomato and potato *PIF7b* genes significantly predated the splitting date between species; while a similar situation was observed for *S. lycopersicum* and *S. pennellii* *PIF8b*. Interestingly, the evolutionary analysis for *PIF7b* demonstrated signatures of positive selection, which can be associated to functional divergence. The absence of *PIF8b* in *S. tuberosum* might be attributed to stochastic gene loss; consequently, no evolutionary analysis was performed.

To explore the functional diversification of tomato *PIF* genes, a comprehensive expression profile was carried out under various physiological processes induced or regulated by light, such as deetiolation, daily cycle, senescence and fruit ripening. Interestingly, *SIPIF* genes displayed differential mRNA accumulation pattern at least along one of the analyzed contexts, suggesting that these genes have undergone functional specification. Little and fragmented information is currently available about the transcriptional regulation of *PIF* genes and only punctual similarities with our experimental conditions were found in literature. The transcription of *AtPIF4* and *AtPIF5* has shown to be upregulated in *Arabidopsis* seedlings upon white light exposure [37]. This result is consistent with our observation that tomato *SIPIF4* mRNA levels increase during deetiolation (Fig 3). Tomato *SIPIF4* and *SIPIF7a* transcript accumulation patterns during diel cycle resemble those observed for *Arabidopsis AtPIF4*, *AtPIF5* and *AtPIF7*, whose mRNA levels are regulated by the circadian clock [38,39]. However, while *AtPIF1* and *AtPIF3* mRNA levels in *Arabidopsis* remained relatively constant along the diel cycle [37], the tomato *SIPIF1a*, *SIPIF1b* and *SIPIF3* oscillated under 12 h/12 h light/dark photoperiod. *SIPIF7b* transcript levels also fluctuated during the diel cycle, suggesting that all tomato *PIFs* are transcriptionally regulated by the circadian clock (Fig 4). Besides the diel cycling, *SIPIF7s* have shown to be exclusively expressed in true leaves (S3 Table), reinforcing their role in circadian response regulation as demonstrated for *AtPIF7* ortholog [40]. Similarities were also found with *Arabidopsis* during dark-induced senescence. In *Arabidopsis*, *AtPIF4* and *AtPIF5* exhibited a peak of transcript accumulation in leaves one day after dark treatment [16] triggering senescence through the activation of the master transcription factor *AtORE1* [17]. Accordingly, tomato *SIPIF4* mRNA reached the highest levels one day after the start of the constant dark treatment (Fig 4). Interestingly, tomato *ORE1* homologs, *STORE1S02*, *STORE1S03* and *STORE1S06* were also induced by the dark treatment, suggesting that a similar functional link between *PIF4* and *ORE* genes regulates dark-induced senescence in both *Arabidopsis* and tomato (S4B Fig). A recent publication functionally characterized tomato *SIPIF1a* demonstrating its involvement as a negative regulator of fruit carotenogenesis [12]. Llorente et al. (2016) reported that *SIPIF1a* expression is induced along ripening and *SIPIF1b* is not expressed in fruits. Our data also showed that *SIPIF1a* transcripts do accumulate during ripening, however, the amount of *SIPIF1b* mRNA at MG stage was 3-fold higher than *SIPIF1a* (S3 Table, Fig 6). These apparent contrasting data might be the results of differences in experimental design, since the transcriptional profile showed here was performed from fruits ripened off vine and under constant light/dark treatments. Moreover, *SIPIF1a* transcript accumulated at higher levels in fruits ripened under light, while *SIPIF1b* transcription was repressed by this treatment. This opposite pattern of light response between *SIPIF1* duplicated genes was also observed in the other physiological contexts analyzed in this work and might be the result from differences in transcriptional promoter activities. Therefore, we surveyed a fragment of 2 kb upstream the translation initiation site of these genes by a *de novo* search for *cis*-regulatory elements. Motifs recognized by *A. thaliana* transcription factors involved in light signaling, such as PIFs and HY5, were found in both sequences. *SIPIF1a* promoter showed PIF and HY5 binding-motifs, PBE-box and CA-hybrid, respectively [41,42]. Additionally, CARG motifs, which are recognized by the ripening inducer transcription factor RIN [43], were also found in *SIPIF1a*

promoter region. CA-hybrid and CARG motifs were also identified in *SIPIF1b* regulatory region together with the HY5-binding ACE-motif (S7A Fig). The presence of gene-specific motifs and, different number and distribution of shared motifs might, at least in part, explain the different transcriptional behavior of *SIPIF1* duplicated genes. In particular, *SIPIF1a* might be target of HY5-mediated light-induction and of the above mentioned PIF autoinhibitory mechanism. The comparison of the mRNA profiles of *SIPIF7a* and *SIPIF7b* duplicated genes was only possible in leaves because in other organs *PIF7* mRNA levels were near or below the detection threshold. *SIPIF7a* and *SIPIF7b* mRNA levels displayed opposite accumulation pattern during diel cycle, while both genes were downregulated by dark-induced senescence, *SIPIF7a* mRNA levels being 10-fold higher than those detected for *SIPIF7b* (Fig 4, Fig 5, S3 Table). In this case, the analysis of the promoter sequences showed also differential number and distribution of PIF and HY5 binding motifs: PBE-box, ACE-motif and CG-hybrid in *SIPIF7a* and; PBE-box and ACE-motif in *SIPIF7b* regulatory region (S7B Fig). To further evaluate differentially selected motifs between these pairs of duplicated genes, a promoter phylogenetic analysis was performed. Resembling the topology of the tree obtained from amino acid sequences, regulatory fragments also revealed that gene duplication predates species divergence (S8 Fig). Interestingly, none of the motifs identified in *SIPIF1s* and *SIPIF7s* is conserved between paralogs, being either *S. lycopersicum* exclusive or shared with *S. tuberosum* and *S. pennellii* orthologs (S9 Fig). These data reinforced that the duplicated genes have undergone functional divergence in the Solanaceae common ancestral.

According to Force et al. (1999) [44], the loss of regulatory subfunctions in the promoter region by mutation and genetic drift is the main process by which duplicated genes are preserved, as long as they retain the complete set of subfunctions from the ancestral gene. In this context, it is expected that the duplicated *loci* should complement each other and show differences at the regulatory region. This model postulates that duplicated *loci* can undergo three different fates: nonfunctionalization, neofunctionalization and subfunctionalization. The first occurs when one copy acquires disabling mutations at the promoter region, leading to gene expression loss, while the other copy remains intact. The second takes place when a copy acquires new regulatory motifs, which confers a new regulatory function to this gene. The last is caused by degenerative mutations at both *loci* leading to loss or reduction of subfunctions. Our observations suggest that *SIPIF1* genes suffered qualitative subfunctionalization, as evidenced by their opposite responsiveness to light, and neofunctionalization, since *SIPIF1a* acquired a regulatory function during fruit ripening. Whilst, *SIPIF7* duplicated *loci* appeared to have undergone quantitative subfunctionalization possibly caused by fixed reduction-of-expression mutations, which resulted in lowered expression of both copies. Moreover, it has been proposed that quantitative subfunctionalization is a transitory state to eventual neofunctionalization [45]. This seems to be the case of *SIPIF7b* gene for which, besides the reduced expression levels described above, positive selection has been also verified. A very interesting mechanism of neofunctionalization of duplicated genes in *Solanum* lineage has been recently described in tomato [46]. While in photosynthetic tissue, a CHLOROPLAST-SPECIFIC LYCOPENE β -CYCLASE (LCY β) mediates the conversion of lycopene to β -carotene, in chromoplast, this reaction is executed by the product of the CHROMOPLAST-SPECIFIC LYCOPENE β -CYCLASE gene (*CYC β*), a *LCY β* paralog. Sequence analysis of *CYC β* gene from a repository of tomato and wild relative accessions showed that *CYC β* undergoes purifying selection in tomato clade. However, the abundant and diverse variations in the promoter region are likely related to regulatory neofunctionalization that played a key role in fruit color development in tomato.

The data presented here bring evidences that *SIPIF* duplicated genes (e.g. *SIPIF1a* and *SIPIF1b*), originated during *Solanum* lineage specific whole-genome triplication, have

undergone sub- and neofunctionalization most likely due to variations in promoter region than in the coding region, disclosing the impact of polyploidization events during the evolution of *PIF* gene subfamily.

Conclusions

Solanum lycopersicum genome harbors eight *PIF* encoding loci, *SIPIF1a*, *SIPIF1b*, *SIPIF3*, *SIPIF4*, *SIPIF7a*, *SIPIF7b*, *SIPIF8a* and *SIPIF8b*. *SIPIF1*, *SIPIF7* and *SIPIF8* duplications occurred during the *Solanum* lineage polyploidization event 71 (\pm 19.4) MYA, prior to the divergence between tomato and potato species. Transcriptional profiling revealed coincident expression patterns between tomato *SIPIF4* and Arabidopsis *AtPIF4* and *AtPIF5*, highlighting the evolutionary conserved function of PIF4 clade. Combined evolutionary analysis and transcriptional profile data indicated that *SIPIF7a* and *SIPIF7b* may have suffered quantitative subfunctionalization that reduced their expression level, followed by neofunctionalization process, supported by the differential pattern of light responsive motifs and the positive selection signatures observed. Finally, *SIPIF1a* and *SIPIF1b* promoter regions showed differential pattern of light and fruit ripening transcriptional factor binding motifs, providing also evidences for regulatory sub- and neofunctionalization. In summary, our data underlined the importance of polyploidization events on *PIF* subfamily diversification.

Methods

Phylogenetic, Gene Divergence Time and Evolutionary Analyses

The amino acid sequences of the five *A. thaliana* canonical PIF proteins (S1 Table) were used as queries to perform a BLAST search against Viridiplantae in Phytozome [47], DNA Data Bank in Japan [48], Dendrome [49], SustainPine [50], Sol Genomics [25] databases. 119 sequences with complete bHLH domain from 16 species, representing liverworts, mosses, lycophytes, gymnosperms and flowering plants, were retrieved. T-Coffee Structural-Alignment algorithm [51] was used to perform an alignment of gymnosperms and flowering plants sequences. The phylogenetic reconstruction was performed by maximum-likelihood method using JTT substitution model and validated by approximate Likelihood Ratio Test (aLRT) with the Shimodaira-Hasegawa-like (SH-like) and 100 bootstrap replicates procedures available at PhyML Interface [52].

Gene divergence time was estimated using $T = dS/2K$ equation, where T is the divergence time, dS is the pairwise synonymous distance calculated in the MEGA 6 software using the corrected Nei-Gojobori method (Jukes-Cantor) [53] and, K is the mean substitution rate estimated for 27 loci belonging to three different chromosomes of *S. pennellii* and *S. lycopersicum* ([28]; 4.38×10^{-9} substitutions per site per year).

Evolutionary analysis was conducted individually for *PIF1a*, *PIF1b*, *PIF3*, *PIF4*, *PIF7a*, *PIF7b* and *PIF8a* genes using the sequences of *S. lycopersicum*, *S. pennellii* and *S. tuberosum*. Non-synonymous (dN) and synonymous (dS) distances and their SE values were estimated with MEGA 6. In order to preserve the reading frames, the alignment gaps were deleted prior to estimation of dS and dN . Codon bias was determined by the effective number of codons (Nc) value computed in the CodonW program [54]. Nc varies between 21 for maximum codon bias, when only one codon is used per amino acid, and 61 for minimum codon bias, when synonymous codons for each amino acid are used at similar frequencies. Three evolutionary models were evaluated using the Codeml program implemented in the PAML4.8a package and the graphical interface PAMLX 1.3.1 [55]. Phylogenetic trees were constructed using manually adjusted alignments of the coding sequences and neighbor-joining method with the optimal model of nucleotide substitution estimated by “Find Best DNA/Protein Model” using MEGA 6 software. To test for neutral evolution, the nearly neutral model (M1a) was compared with the

null hypothesis, one ratio model (M0). To test positive selection, the model M2a was compared with M1a. The M0 model assumes that all codons across the sequences have the same level of dN/dS . The model M1a proposes that there two classes of codon, some with $0 \leq dN/dS < 1$ and the remainder with $dN/dS = 1$. Finally, model M2a divides codons into three classes: those with $0 \leq dN/dS < 1$, $dN/dS = 1$, and $dN/dS > 1$. The fit of model M1a versus M0 or M2a versus M1a is evaluated by a likelihood ratio test (LRT) comparing twice the difference in log likelihoods with a χ^2 distribution [56]. In M1a versus M0 and M2a versus M1a the degrees of freedom (df) are 1 and 2, respectively. Bayes empirical Bayes (BEB) analyses were performed to identify positively selected residues with a BEB posterior probability 95%.

Gene collinearity was addressed by BLASTN search against tomato genome [25] using the CDS sequences within a window of 100 Kb upstream and downstream the *SIP1F1*, *SIP1F7* and *SIP1F8* duplicated genes as queries.

Plant Material

All the experiments were performed with *Solanum lycopersicum* (cv. Micro-Tom). For deetiolation, diel cycle and dark-induced leaf senescence experiments, tomato seeds were surface sterilized and directly sown *in vitro* as described by Lira *et al.* [57]. After 120 h pre-germination in absolute darkness, seedlings were transferred to specific treatment conditions as described below. For deetiolation experiment, seedlings were either transferred to continuous white light ($\sim 100 \mu\text{mol m}^{-2} \text{s}^{-1}$) or maintained in absolute darkness for 0, 24, 48 and 72 h, after which cotyledons and hypocotyls were separately harvested. For daily cycle experiment, plants were grown under 12 h/12 h light/dark ($\sim 300 \mu\text{mol m}^{-2} \text{s}^{-1}$) photoperiod for three weeks and the second fully expanded leaves were harvested every 4 hours, for 24 hours. For dark-induced senescence, plants were grown in the same conditions as the daily cycle experiment and subsequently the plants were transferred to darkness for 0, 1, 2, 3 and 7 days for inducing leaf senescence. The second fully expanded leaves were harvested 4 h after the beginning of the light period since this day point has been shown to exhibit the highest mRNA levels of most tomato *PIF* genes. All experiments were conducted at $25 \pm 1^\circ\text{C}$.

For fruit ripening experiments, plants were grown in 1 L pots in a greenhouse under automatic irrigation, at an average mean temperature of $25 \pm 2^\circ\text{C}$, 11.5 h/13 h (winter/summer) photoperiod and $250\text{--}350 \mu\text{mol m}^{-2} \text{s}^{-1}$ PAR irradiance. Fruits at MG stage were harvested about 30 days after anthesis (dpa) and were transferred to continuous white light (400 to 800nm, $\sim 50 \mu\text{mol m}^{-2} \text{s}^{-1}$) or maintained under absolute darkness until reaching distinct ripening stages in a temperature-controlled growth chamber maintained at $25 \pm 2^\circ\text{C}$ and air relative humidity at $80 \pm 5\%$. Top and bottom illumination was applied in order to homogenize the light environment surrounding the fruits. Since the beginning of the treatments, fruits were placed into a 0.5 L sealed transparent vessel and continuously flushed with ethylene-free, humidified air (approximately 1 L min^{-1}) in order to avoid accumulation of ethylene inside the containers. Pericarp samples (without placenta and locule walls) were harvested at MG (displaying jelly placenta, 2 days after harvesting), BR (breaker), one day after BR (BR1), three days after BR (BR3), six days after BR (BR6), twelve days after BR (BR12) stages.

Seedling, plant and fruit tissues were harvested either under the specific light conditions used for the treatments or under dim green light ($\sim 0.01 \mu\text{mol m}^{-2} \text{s}^{-1}$), as appropriate. All samples were harvested and immediately frozen in liquid nitrogen, powdered and stored at -80°C .

Chlorophyll and Carotenoid Measurement

Chlorophyll and carotenoid extraction and analysis were carried out as described by Lira *et al.* [58]. When a data set showed homoscedasticity, an ANOVA test followed by a Tukey test ($P <$

0.05) was used to compare genotypes and fruit developmental stages. In the absence of homoscedasticity, a non-parametric ANOVA test was performed by applying the Kruskal–Wallis test ($P < 0.05$).

RNA Extraction and Quantitative Polymerase Chain Reaction (qPCR) Analysis

RNA extraction, cDNA synthesis and qPCR reactions were performed as described by Quadrona et al. [59]. The primers used for qPCR are listed in S4 Table. All reactions were performed with two technical replicates and at least three biological replicates. mRNA levels were quantified using a 7500 Real-Time PCR system (Applied Biosystem) and SYBR Green Master Mix (Applied Biosystem). Absolute fluorescence data were analyzed with LinRegPCR software [60] to obtain Ct values and to calculate primer efficiency. Expression values were normalized to the mean of two constitutively expressed genes: GAGA and CAC for seedlings [61], TIP41 and EXPRESSED for leaves and CAC and EXPRESSED for fruits [59]. A permutation test lacking sample distribution assumptions [62] was applied to detect statistical differences ($P < 0.05$) in expression levels between mutants and the control using the algorithms in the fgStatistics software package [63]. For senescence analysis, the normalized expression pattern was presented by a heat map constructed with GENE-E program [64].

Promoter Analysis

A 2 Kb fragment of the promoter sequences of *PIF1s* and *PIF7s* were retrieved from Sol Genomics Network [25]. The presence of transcription factor binding motifs was analyzed in *S. lycopersicum* sequences using PlantPAN 2.0 platform [65]. The promoter regions were aligned using T-Coffee Structural-Alignment algorithm [51] and the Neighbor-Joining tree was reconstructed with 100 bootstrap replicates and p-distance implemented MEGA 6 [53].

Supporting Information

S1 Fig. Phylogenetic reconstruction of PIF protein family. Phylogenetic analysis of PIF protein subfamily in Viridiplantae performed with 112 sequences from 13 species. Accession numbers of all sequences are detailed in S1 Table. Numbers at nodes represent bootstrap/approximate likelihood-ratio test (aLRT) values.
